Vol. 182, No. 4640 2nd. pt. SATURDAY, OCTOBER 4, 1958 Dec. 3s. 6d.

METROVAC VACUUM GAUGES

For the pressure range
1.0 mm. Hg. to 10^{-7} mm. Hg.

In addition to the Penning gauge and control unit shown, discharge tubes and gauges of the Pirani, thermocouple and ionisation types are available.

The Metropolitan-Vickers range of scientific equipment includes apparatus for the investigation of metallurgical, chemical and biological problems in research, production or processing.

A DICTIONARY OF NAMED EFFECTS AND LAWS in Chemistry, Physics and Mathematics

by

D. W. G. BALLENTYNE, B.SC., & L. E. Q. WALKER, A.R.C.S.

Size: 8½ in.×5½ in. *232 pages.* *Illustrated* *30s. net.*

Intended as a desk reference work for research workers and graduates, this book gives a concise explanation of many phenomena which are referred to by the name of their discoverers. It thus saves the reader a great deal of time which would otherwise be spent in searching for the information in specialist works.

A New John Wiley Book

THE GENETIC BASIS OF SELECTION

by

I. MICHAEL LERNER
(University of California)

Size: 9½ in.×6 in. *314 pages.* *Illustrated* *64s. net.*

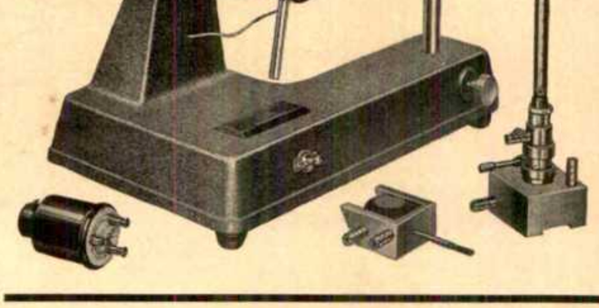
This work is designed for the reader who has a thorough knowledge of modern genetics but lacks an extensive background in mathematics and statistics. It discusses diploid sexually reproducing populations and deals in detail with the intraspecific level of biological organisation.

37 ESSEX STREET, LONDON, W.C.2

PRECISION INSTRUMENTS

RB14

Pulfrich Refractometer



fitted with circle divided on glass and giving readings on opposite sides of the circle to 5 seconds, by double microscope

This instrument possesses many advantages over the older type of Pulfrich refractometer and is used in all parts of the world for testing oils, optical glass, chemicals, drugs, etc.

We shall be pleased to demonstrate this instrument and give any advice as to its use, by appointment at our Works.

REDUNDANCY IN INDUSTRY

IN a notable speech opening a long debate on the economic situation and wages at the Trades Union Congress on September 4, Mr. Alan Birch, chairman of the Congress's Economic Committee, after remarking that the trades unions' record of productivity was good, asked whether it was not true that too often co-operation and new methods in industry were regarded by the unions not so much as a positive thing for their own benefit, but as a concession to the employers. He suggested that the trades unions should use their organization to demand efficient organization and management, as well as to obtain a fair share in remuneration. He recognized that this meant a positive rather than a negative approach and that if the trades unions were to deal with the new problems posed to-day there must be a break with the approach developed when the unions were being built up and were on the defensive. Their industrial, economic and emotional approach must be based on the experience of the past two decades and not on that of previous ones.

Mr. Birch's views appeared to find little support in the general body of the Congress, but they are firmly supported by a study of redundancy, one of the problems specifically mentioned by Mr. Birch, which the Acton Society Trust has recently published*. This introductory survey of problems and practices associated with redundancy has been sponsored by the Society as part of its general plan of work, which seeks to obtain accurate factual knowledge about important contemporary developments in our industrial society so as to facilitate our understanding of the effect of such developments on individuals—their lives, their liberties, their values. Some of these problems arise from the increasing dependence of our industrial efficiency upon change and flexibility, and it is here that what have come to be known as problems of redundancy arise. Moreover, these are often very real human problems which must be handled with sympathy and understanding if, in a liberal society, progressive economic efficiency is to develop soundly.

In this study of the causes of redundancy, which is clearly distinguished from unemployment, its relation to the mobility or immobility of labour, its effect on individuals, and the measures which are being or could be taken to reduce the costs, material and psychological, which redundancy imposes, the Acton Trust is clear that the trades unions have a major responsibility. Redundancy is the involuntary loss of a job through no fault of the worker concerned. Since the redundant worker may be able to go straight into another job, it is not necessarily the same as unemployment; moreover, the unemployed will include some who have been dismissed for personal defects or have left of their own accord, and yet others who are seeking their first job. The problems of redundancy may indeed be sharpened by a depression, but throughout this survey it is assumed that full employment policy, in the sense of the maintenance of a general balance between the supply and demand for labour, is being successfully pursued.

Traditionally, the primary responsibility for coping with the effects of redundancy is the worker's own, and, in spite of arguments that it should not be his exclusively, it remains true that the responsibility for managing one's own life is inherent in the preservation of individual freedom. Nevertheless, it is consistent with this, and realistic, to argue that the trades unions have a major responsibility: on one hand, they should accept the inevitability of some redundancy, especially when a forward wage policy has produced an economy of increasingly costly man-power; and on the other, they should accept the responsibility for co-operating in handling redundancy so as to minimize hardship. Nevertheless, the survey fails to suggest that trades unions have been unreasonably backward in negotiating redundancy agreements. This may have been due to the backward view which Mr. Birch condemned, but it could also be due to the belief, held by employers as well as trades unions, that redundancy is often better handled at a local, rather than a national, level.

The Acton Society Trust makes two suggestions as to how the trades unions might help to reduce hardship and to encourage the best utilization of our resources. First, it suggests that the unions might pay greater attention to securing some form of protection against redundancy for their members, so as to safeguard them and make them less fearful of technical change. For example, the unions might negotiate a plan for compensation as a form of deferred pay, possibly safeguarded by establishing a redundancy fund. Secondly, and highly pertinent in the context of recent events, it is suggested that some attention should be given to the position of coloured people when redundancy occurs. The Trust regards this as a question about which the unions should make up their minds and then educate their members.

By and large, so far as the unions are concerned, their immediate contribution to the problem of redundancy seems to be a matter of education and a new outlook, and it once again indicates the critical importance of education, and especially of technical education. For the present, the survey stresses rather the responsibility of government and of industry. The former is regarded as having three aspects: the framing of general institutions and enactments where these impinge on industry so as to encourage rather than hamper the mobility of labour; the active assistance of mobility where public agencies can do so effectively; and the guaranteeing, as part of the general obligation of the Welfare State, of a minimum standard of living, through unemployment insurance and national assistance.

---

* Redundancy: a Survey of Problems and Practices. Pp. vi+56. (London: The Acton Society Trust, 1958.) 5s.

It is on the degree of responsibility of employers that opinions differ most widely, but before considering the Trust's comments here and its further suggestions regarding the role of the Government, it is as well to consider what is implied in the objectives of a redundancy policy. The evidence of this survey suggests that hardship can best be reduced by paying special regard to the most vulnerable groups, particularly those in their late forties and early fifties, assisting people to get new jobs and helping them in the transition period. The second objective, that of encouraging the best utilization of man-power, can be achieved partly by making it easier for people to be mobile, especially geographically, and partly by bringing work to the workers where this is feasible.

The specific ways in which it is suggested that Government could further the achievement of these objectives are, first, through legislation, which requires employers to take such action as paying compensation or giving longer notice, the latter being possibly the more desirable. It might also be worth while to consider the feasibility of an insurance scheme to meet the contingency, and such a scheme might encourage a more responsible policy to redundancy and lay the real costs of uncertainty and instability where they properly belong. Secondly, changes in unemployment-pay, such as a higher initial benefit or the introduction of different contributions and benefits based on difference in earnings, as is done in Germany and Canada, is suggested, while fuller use and less-rigid application might well be made of the existing schemes for payment by the Ministry of Labour, in 'designated' circumstances, of removal expenses, fares and lodging allowances.

In its remaining suggestions for the role of Government, the pamphlet touches on joint responsibility with the employers and with the trades unions, and in both cases we are concerned with education. The publication, "Positive Employment Policies", issued earlier in the year by the Minister of Labour, is an example of what Government can do to exhort or educate employers to adopt responsible and adequate policies, while even more specifically the Ministry's training scheme depends on the goodwill of both the trades unions and the employers. The use of the scheme depends indeed on a more co-operative and progressive attitude on their part; it is a matter not simply of training or re-training the workers affected but of educating both unions and employers to face the responsibilities and new demands of technological change and development.

As regards the role of the employer, the Acton Society Trust takes the view, widespread and gaining ground among employers, that a firm is a social as well as an economic organization, with responsibility not only to its shareholders, but also to its workers, its customers, and to the wider community of which it forms part and through which it exists. In the light of this conception, three main points are made. First, with careful planning of man-power, the effects of redundancy can often be avoided or reduced, and even where this is not possible, longer notice can be given. Secondly, the employer, and especially the larger employer, can obtain information far more readily than the individual worker and therefore do much to assist and supplement the Ministry of Labour's efforts to find him other employment. Thirdly, in employing a man, employers incur not simply a liability to pay him for his work as it is performed week by week, but equally a liability to build up a reserve fund in respect of each man to cover either the employer's contribution to a pension or some form of compensation in the event of termination of employment before pension age is attained. The greatest need seems to be to endeavour to protect the older and most vulnerable employees through early pensions, or higher compensation where it is necessary to discharge them.

Employers can obviously help to reduce hardship by making, as some companies do, tide-over payments until a man has found a satisfactory job, and the survey finds some evidence of the great lengths to which some employers will go to ensure that the basis of dismissal is fair. It seems equally clear that there is room for such personal interest or touch and that its existence can make a most valuable contribution to the removal of hardship and any sense of dissatisfaction.

Finally, the pamphlet discusses the implication of the Government's policy for the distribution of industry and its bearing on mobility. Here it makes some sound remarks on the community aspect of the problem and points out that the failure to deal rationally with the reform of local government has hindered the dealing with the distribution of industry on its economic merits. It is too early to judge the effect of the Development of Industry (Industrial Finances) Act, though it is regarded as a useful addition to a development area policy which has become too rigid to meet present-day requirements.

Here, as well as the outstanding impression left by this preliminary survey, is the continuing need for fresh thinking and readjustment to changing conditions. Largely it is true that the initiative must rest with the Government, but the task of education required both to secure the essential mobility, the re-training and adjustment of labour to new occupations, the removal of restrictive and obsolete practices that hinder transfer and adjustment, is immensely varied and demands clear understanding and close co-operation on the part of both the unions and the employers. The vital importance of both technological and technical education is once again to be seen, both as a contribution to the supply of management of the high quality and wide outlook demanded, and to the supply of technicians and craftsmen, as well as technologists, of the flexibility and adaptability which an age of rapid technical change requires. It is, above all, on the vision and energy and urgency with which the expansion of technical and technological education is pursued that the ability of Britain to solve the problems of redundancy and to maintain its industrial efficiency ultimately depends.

SCIENCE TEACHING IN SECONDARY SCHOOLS

The Teaching of Science in Secondary Schools

Compiled by a Joint Committee of the Incorporated Association of Assistant Masters and the Science Masters' Association. Second edition, revised and reset. Pp. ix+274. (London: John Murray (Publishers), Ltd., 1958.) 17*s*. 6*d*. net.

THE original edition of this book dealt, in a practical manner, with every aspect of science teaching in the grammar type of secondary school. In the present edition every chapter has been revised thoroughly and the work is, in fact, a new book.

The original edition was the outcome of several years work by a committee which had the help of two hundred corresponding members. The present edition likewise is the fruit of the work of several years. Its appearance is timely, since so much thought is being devoted to the extension of science-teaching and to the place of science in the school curriculum. In particular, the new edition will prove most valuable because of the immense fund of practical experience available to the compilers on the design and equipment of laboratories and science rooms. When new schools are built or old schools are improved, teachers who act in a consultative capacity will find in this book a useful guide towards a solution of the problems which beset modern teaching laboratory design.

The work begins with a short history of science-teaching, and it is hoped that the future will see a separate volume dealing with the 'comparative' history of science teaching. It is useful to envisage the present system, with its difficulties and imperfections, through its history.

In the following chapter the aims of science-teaching are clearly stated. This is important, since so many so-called aims of education are entirely idealistic and theoretical. A pleasing feature of the book throughout its pages is that it keeps its feet firmly on the ground. Whereas the cultural value of science is stressed, its place in the competitive extra-mural world of technical achievement and economic survival is not forgotten.

Subsequent chapters deal in detail with the time desirable and available each year of the school course for teaching science, and the practical needs in the form of laboratories, demonstration, store and other rooms for schools of various sizes; plumbing, lighting, heating, ventilation, water, gas and electricity supplies are all considered in an expert manner. Even the acoustics of science rooms, floor materials, wall surfaces, doors, hatches and blackboards have reasonably adequate treatment.

There follows a chapter packed with information, presented succinctly, on apparatus and its maintenance, materials and safety precautions. Various methods of science-teaching are discussed and there is a very useful chapter on advanced-course work and preparation for university entrance. This is particularly valuable since the sixth forms of many smaller grammar schools are not adequately equipped, in materials and staff. A useful warning is given concerning the dangers of neglecting the mathematical background of the school sciences. Other sections deal with examinations, visual and other teaching aids, science in rural schools, first aid in the laboratory, the supply and training of science teachers, the science teacher and the law. The work concludes with a comprehensive bibliography.

There are some sensible and encouraging remarks on the training of science teachers, though one wonders where men and women with all the qualities and qualifications, given as necessary for the teacher of potential teachers, can be found.

The aims of 'methods' lecturers in science are two-fold: "first, there is the immediate aim of suggesting to the beginner appropriate methods of approach, describing good techniques for handling material so that it may make its full contribution to the education of the pupils. Secondly, the 'methods' lecturer is often faced with the task of doing his best to correct the unfortunate bias of some university courses. For instance, in many universities students are turned out without any knowledge of laboratory technique and are entirely ignorant of the subject in which they have been trained. The university course often concentrates on teaching skills and techniques applicable mainly to elementary research. The 'methods' lecturer endeavours to correct this by emphasizing the social and historical bases of science and by stimulating thought on more fundamental problems concerning the implications of science".

Not only should every teacher and potential teacher of science know this important book; but also it should be read by every head teacher and educationist with administrative, authoritative or senior status.

W. L. Sumner

ENZYMES AND RELATED TOPICS

Advances in Enzymology and Related Subjects of Biochemistry

Edited by F. F. Nord. Vol. 18. Pp. v+435. 9 dollars. Vol. 19. Pp. v+457. 9.85 dollars. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.)

THESE two volumes contain a pleasing selection of the several types of review for which "Advances in Enzymology" have acquired such an excellent reputation. Of the fourteen articles, two are detailed accounts of work on a single pure enzyme; seven discuss enzymes in connexion with particular metabolic systems, such as the tricarboxylic acid cycle, photosynthesis, or nitrogen metabolism; three are not specifically concerned with enzymes, but with related topics, namely, cytochromes, lipoic acid, and deoxyribonucleoprotein; and one deals with a group of enzyme inhibitors. In addition, the compilers of these volumes have followed an early tradition of including an occasional article on a process in which enzymes must surely be involved, although as yet virtually nothing is known of the enzymic stages; in this instance by including an article on lignification.

In Volume 18 the pure enzyme discussed is succinic dehydrogenase. Drs. Singer, Kearney and Massey give a clear account primarily of their own recent work on the purification and properties of this flavoprotein. Particularly interesting is their discussion of the role in this system of the iron associated with the flavin group; they suggest that the iron may be functional in some reactions catalysed by the enzyme but not in others. Next to this article is an excellent review by Dr. E. F. Hartree of the cytochromes in higher plants, most of which, of course, function enzymically in oxidation systems. It collects together all the work on the occurrence of cytochromes in various plant tissues, from the early classic work of Keilin and his collaborators to the more recent discovery of specialized plant cytochromes such as *f* and b_7. The function of these cytochromes as terminal oxidases, in photosynthesis, and in the transport of ions, is discussed in some detail.

Sir Rudolph Peters, in an account of the "Mechanism of the Toxicity of the Active Constituent of *Dichopetalum cymosum* and Related Compounds", develops the thesis that fluoroacetate and its analogues inhibit carbohydrate metabolism by a process of 'lethal synthesis', the enzyme inhibitor produced being fluorocitrate. The tricarboxylic acid cycle is also dealt with in a review, in French, by Prof. J. M. Wiame, on the importance of the cycle in biosynthesis, primarily in micro-organisms.

A very valuable article is that of Dr. H. L. Kornberg on "Pyrophosphorylases and Phosphorylases in Biosynthetic Reactions". It collects together into a logical system the considerable number of enzymes which have come to light in recent years which act on phosphorylated compounds at the phosphate linkage, either by transferring the phosphate or the remainder, or in a more indirect way bringing about the synthesis of a new compound at the expense of the energy of the phosphate linkage. There is a limited amount of detail about individual enzymes in the group, but very useful discussion of the possible intimate mechanisms involved.

Other articles in this volume are by Dr. L. J. Reed on "The Chemistry and Function of Lipoic Acid", by Drs. Butler and Davison on deoxyribonucleoprotein, by Dr. W. O. James on the respiration of higher plants, and by Drs. Schubert and Nord on lignification in higher plants.

Turning now to Volume 19, the article on the properties of a pure enzyme is by Drs. Kimmel and Emil Smith, on papain. This enzyme is of considerable commercial importance ; it was unknown to the present writer, until he read this account, that 500,000 lb. of crude papain, the product of more than 2 million papaya trees, are imported annually into the United States alone. It is also of considerable academic interest, since papain can be easily purified, especially as a mercury salt, and is a small molecule with a single peptide chain of 180 residues. These properties, together with the ease with which quantitative studies of its enzymic activities can be carried out, make it specially suitable for an attempt to relate protein structure and enzyme activity. Prof. Smith has himself made striking contributions to this end ; he has shown, in particular, that 120 ± 10 of the 180 residues can be removed from the N-terminal end of the chain without loss of all the enzyme activity. In this article, a plausible reaction mechanism is put forward on the basis of such studies.

Enzymic reaction mechanisms are also discussed at length in the review by Dr. H. S. Mason on "Mechanisms of Oxygen Metabolism". This long and in parts difficult account of enzymes 'activating oxygen', especially those introducing hydroxyl groups into cyclic compounds, contains a good deal of theory and speculation. It should prove very stimulating to those working in this field, and may provoke further experimentation along lines which will clear up the many present difficulties, especially the role of reduced coenzymes I and II in the action of hydroxylating enzymes.

Nitrogen metabolism is reviewed (in French) by Prof. Braunstein, of Moscow. He refutes the common idea that amino-acid metabolism involves simply the oxidative deamination of all amino-acids to give ammonia, which is immediately converted to urea. There is, in fact, a complex pattern of amino-acid metabolism analogous to the glycolytic and tricarboxylic acid pathways of carbohydrate metabolism. As well as a historical survey of earlier work, recent Russian work on the importance of vitamin B_6, together with some comparative studies on deamination, is presented. The activation of amino-acids is discussed, in German, by Prof. Wieland and Dr. Pfleiderer, who, among other things, give a good account of the chemistry of S-acyl derivatives of amino-acids, aminoacyl phosphates, and aminoacyl-adenosine-5′-phosphates.

The remaining article, actually the first in the volume, is by Drs. Vishniac, Horecker and Ochoa on "Enzymic Aspects of Photosynthesis". This contains, as well as a discussion of photosynthesis itself, a good survey of the known location in plants of the enzymes and coenzymes of carbohydrate metabolism as elucidated in animal tissues. This part of the article supplements that of Dr. James in Volume 18 already noted. The Calvin mechanism for carbon dioxide fixation, which has been reviewed elsewhere, is discussed at some length, but the emphasis is usefully laid on the occurrence of the enzymes involved.

Both Volumes 18 and 19 of "Advances in Enzymology" were published in the same year, and it is apparently the intention of the publishers to increase the previous frequency of one volume per year. This should enable them to keep them down to the present handy size. All in all, these two volumes maintain the high standard which dates from Volume 1 in 1941.

EDWIN C. WEBB

5-HYDROXYTRYPTAMINE

5-Hydroxytryptamine

Proceedings of a Symposium held in London on 1st and 2nd April, 1957. Edited by Dr. G. P. Lewis. Pp. xvii + 253. (London and New York : Pergamon Press, 1958.) 60*s*. net.

THIS is an account of a two-day international meeting organized at the instigation of the Co-ordinating Committee for Symposia on Drug Action. It was held at the Wellcome Foundation, London, in April 1957, and was the third meeting of this type, the earlier ones being on histamine and on hypertensive drugs. Nearly fifty research workers took part, and they included pharmacologists, physiologists, biochemists, pathologists and experimental psychiatrists.

5-Hydroxytryptamine is a substance of potent biological activity which is widely distributed in living organisms, being found in plants as well as in various species of animals. It occurs in many tissues, including blood platelets, intestinal mucosa, carcinoid tumours and in a number of vegetable and animal stings and venoms. This book contains a striking picture of the 'sting-print' of a nettle, made by pressing the leaf on filter paper and developing the spots of 5-hydroxytryptamine by chemical means. In this connexion, it is interesting to find that its biological activity is strongly antagonized by extracts of dock (*Rumex*) leaves. The symposium was divided into a number of sessions (with different chairmen as indicated), which dealt with the occurrence of 5-hydroxytryptamine (Sir Charles Harington), its metabolism and its cardiovascular actions (Dr. W. Feldberg), its other actions—concerned with nerve endings and ganglia, carcinoids, anaphylaxis and gastric secretion (Dr. Marthe Vogt), antagonists to its peripheral and central actions (Dr. B. B. Brodie), ending with a general discussion (Prof. J. H. Gaddum). Each group of papers was followed by its own discussion. It has sometimes been questioned whether, in symposia of this type, the reporting, more or less verbatim, of the spontaneous discussions is worth while. It was certainly worth while in the present symposium, for the discussions were lively, good-natured and free from trivialities but not from humour; moreover, they included a good deal of unpublished experimental material.

The volume is very well produced. It has an index —very brief, but better than none—and there are useful bibliographies at the end of the sections. The work on 5-hydroxytryptamine is scattered over a wide range of journals and it is valuable to have the more important findings collected together and discussed in this volume. D. C. HARRISON

FOSSIL MAMMALS

Traité de Paléontologie

Publié sous la direction de Prof. J. Piveteau. Tome VI: Mammifères: Évolution. l'Origine des Mammifères et les Aspects Fondamentaux de leur Évolution. Deuxième volume. Pp. viii+962 (1040 figures et 1 planche). (Paris: Masson et Cie., 1958.) Broché, 15,500 francs; cartonné toile, 16,500 francs.

THIS encyclopaedic work treats of the fossil placental mammals, except the Carnivora, Cetacea and Artiodactyla, which come in the first volume, and the Primates, which are allotted a separate Tome VII. Despite the title, there is nothing about the origin of mammals in the present volume, where the histories of some twenty-five orders, separate since the early Tertiary, are recounted in considerable detail, including a description of every genus.

Many of the contents have already appeared in an abridged form in Grassé's "Traité de Zoologie": the article on Proboscidea is reprinted verbatim from that work. Some sections, however, are new, notably J. Viret on the Perissodactyla, which is of a high standard; R. Hoffstetter on the Xenarthra, an excellent account; S. Schaub on the Simplicidentate rodents, which develops in full the classification already used in the "Traité de Zoologie", and R. Saban on the Insectivora, which uses a new classification. Mlle. C. Dechaseaux has contributed useful articles on endocranial casts, including some new material. There are also some interesting articles by Prof. Piveteau on drawings made by Palaeolithic man.

Together, these articles form a compendium of existing knowledge which will be of great value as a work of reference, particularly to research workers. The numerous illustrations will be especially useful to the advanced student, and the extensive bibliographies provide an excellent guide to the literature. However, the detailed treatment tends to obscure the evolutionary picture: the reader becomes overwhelmed by generic distinctions, and the authors have, on the whole, not taken sufficient opportunity to present synoptic and critical interpretations of the data. They are not altogether to blame: a considerable proportion of the fossil mammals are so poorly known that there is little on which to base an opinion of their relationships, and in many cases where the direction of evolutionary change has been established it has not been analysed functionally and ecologically.

Perhaps one of the principal functions of a survey such as this is to reveal gaps in knowledge and suggest lines for future research. It is not surprising that the phylogeny of the rodents and insectivores should be much less well understood than that of large forms like the Perissodactyla, but it seems anomalous that the order Proboscidea, where fossil material is relatively abundant and the general direction of evolutionary change is well known, should be classified on a frankly artificial basis. The predominance of teeth and jaws in the interpretation of fossil mammals becomes very evident when glancing through the illustrations in this volume, but functional interpretations of the dentition are noticeably lacking.

A work on so large a scale must inevitably be somewhat out of date by the time it is published. Few papers that have appeared since about 1955 have been incorporated fully, though a number are included in the bibliography. Recent work indicates that many of the primitive early placentals that have hitherto been classed as Insectivora are not closely related to the existing members of that group.

P. M. BUTLER

THEORETICAL GENETICS

An Introduction to Genetic Statistics

By Prof. Oscar Kempthorne. (A Wiley Publication in Applied Statistics.) Pp. xvii+545. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 102*s*. net.

THE division is already familiar of physics—and physicists—into the theoretical, or mathematical, and the experimental; and it is becoming so in chemistry, too. Among the biological sciences, there can be little doubt that genetics will be the first to go this way and indeed there have been signs that it has begun to do so, for mathematical treatments of theoretical problems are no novelty in the genetical literature. Dr. Kempthorne's book marks a further significant step in this direction.

In so far as the title, "An Introduction to Genetic Statistics", suggests an account of the statistical methods used in tests of significance and the estimation of genetics parameters, it could be misleading. True, these methods are described, at times in some detail; but the bulk of the book is devoted to the mathematical development of genetical concepts, theories and problems. Mating systems, inbreeding, and population problems are all covered, often in a wealth of detail. Thus inbreeding systems are handled both by what may be termed the direct method, which Malécot has largely developed, and by matrices, these being used as an introduction for the geneticist to matrix algebra. To many, however, the great appeal of the book will be its very full treatment of the theory of biometrical genetics both in populations and in the descendants of deliberately crossed inbred lines. The treatment is always as general as the author can make it, often going well beyond anything that has yet been thrown up by experiment, and indeed a considerable body of new work is here presented for the first time. Some topics, for example genotype-environment interactions, do, however, appear thus far to have eluded Dr. Kempthorne's interest.

The author says that "the prerequisites of the book are essentially nil if . . . all readers will have had high school algebra". He surely over-estimates either the content of "high school algebra" or the progress achieved by the average geneticist during his school days. Few, in fact, will fail to find Dr. Kempthorne's text to be hard going, and many geneticists will undoubtedly give it up in despair. They will, however, be the losers if they do so. It is essentially a theoretical mathematical treatise: arithmetic is seldom used and never where algebra can be made to serve. Experimental data are at a discount. The level of genetics assumed appears to be lower than the level of mathematics, and the genetical definitions are commonly less precise than the mathematical. The mathematically more elementary chapters are so much more scrappy than the advanced that one inevitably feels the author to have found them so much less interesting to write. The occasional biological gloss, as where a footnote asserts that bees, oysters and snails may be self-fertilizing like plants, gives an impression of archness rather than of accuracy or understanding. But this should neither surprise nor irritate, for Dr. Kempthorne is a mathematician. Rather, we should be grateful that he has devoted his mathematics to developing genetics in a way which all but the merest few geneticists can but accept without hope of emulation. The result is neither elementary nor easy. It will seldom be read for pleasure. But it cannot fail to command respect as a source of constant and indispensable reference for all concerned with the theory of population and biometrical genetics; and it cannot fail to make one wonder how long away is the day when we must recognize, albeit regretfully, that theoretical and experimental genetics have become different, though cognate and complementary, disciplines and skills.

KENNETH MATHER

ANTARCTIC METEOROLOGY

Meteorology of the Antarctic

Edited by M. P. van Rooy. Pp. xi+240+8 plates. (Pretoria: Weather Bureau, Department of Transport, 1957.) n.p.

DURING the past ten years the South African Weather Bureau has done much for Antarctic meteorology. The Royal Naval Weather Service had shown that a useful synoptic chart could be drawn, and the Weather Bureau finds that in spite of shortage of data from some areas a reasonably good chart can be drawn for the whole of the southern hemisphere, especially during the whaling season when the factory ships make regular reports from the higher latitudes. It has not been able to undertake the labour and expense of issuing a daily analysis, but since 1952 it has published basic data for climatological studies and research in its own journal, *Notos*. One of its aims has been to persuade meteorologists from the northern hemisphere to take a more active part in the work, and the new compendium is intended to give as much help as possible to those engaged on expeditions to Antarctica during the International Geophysical Year. It includes a useful account of the main geophysical features and climates of the Antarctic continent, islands and surrounding ocean and of what is known of the surface currents. It shows where previous meteorological data can be found and deals with the special problems of observing under Antarctic conditions.

Discussion of the available data occupies most of the book. W. L. Hofmeyr, studying the distribution of atmospheric pressure at sea-level, directs attention to the deep circumpolar trough all around the Southern Ocean centred in about 62° S. in summer and 64° S. in winter, and tending to be farther north in the Atlantic sector than in the Pacific sector. The only counterparts in the northern hemisphere are the oceanic lows over Iceland and the Aleutians; elsewhere the effect of the land-masses tends to equalize the north–south gradient. The charts accompanying the work seem to indicate a weak tendency for similar smoothing in sectors of the Antarctic where the continental coast has its strongest north–south trend. It is shown that the anticyclone over the continent should be considered as a prevailing but not uninterrupted condition, since wandering cyclones can enter it.

Dr. Loewe shows that existing information about precipitation and evaporation is inadequate for a study of the balance between them. Apart from the scarcity of observing stations and absence of regular shipping lanes, the difficulties of measuring rainfall at sea and snowfall on the continent are very formidable. E. Vowinckel's study of the climate of the Antarctic Ocean gives a clear indication that the ocean currents and surface temperatures are the predominant factors; the same is true for the islands the climates of which are usefully outlined in the next chapter. Around the coast of the continent the differences between one region and another seem to depend more on varying exposure to continental and oceanic influences and on seasonal changes in the limits of the pack-ice. The variation is particularly great in the Graham Land region. This area is given special attention because of the greater abundance of observations. A pioneer chapter by W. L. Hofmeyr on the upper air conditions shows that the circulation pattern is simpler than that of the northern hemisphere and the heat exchange between the pole and lower latitudes appears to be less effective. A final chapter deals with the history and problem of weather map analysis. In listing the twelve deepest lows that have been recorded south of 50° S., it overlooks one of 927·7 millibars reported by the R.R.S. *Discovery II* from the Bellingshausen Sea on October 30, 1932, second only to 923 millibars reported from Adélie Land in September 1951.

The folding map which accompanies the book is not always identical in detail with other recent publications and its contours, though tentative, may give too positive an indication of the postulated Ross–Weddell Graben. The map overlooks the existence of Peter I Island, which would be a more useful station than some of those in Graham Land. The eleven chapters and references constitute a very valuable compendium.

Although Antarctic meteorology is being continually furthered in a qualitative way by skilful arrangement of the growing wealth of data, the work has to be done with rather superficial guidance from physical principles. Even in the northern hemisphere, where there is a close network of observations, meteorologists have emphasized the growing belief that we might do better in the long run by trying to find out what kind of behaviour the laws of Nature prescribe. In the Antarctic, where it is difficult to get more observations, such guidance seems very desirable. The relatively simple arrangement of land and ocean favours systematic physical study. To make much progress the atmosphere and ocean must be studied together, and qualitatively the Antarctic Ocean is known as well as if not better than the atmosphere. Results of universal importance might readily be obtained there, but the work would involve a joint meteorological and oceanographic expedition to the ocean rather than to the land, including studies of the transfer of heat and momentum, and quantitative investigations of the circulation of the deep water as well as that of the upper air. G. E. R. Deacon

ANNUAL REVIEW OF PHYSIOLOGY

Annual Review of Physiology, Vol. 20

Edited by Victor E. Hall, in association with Frederick A. Fuhrman and Arthur C. Giese. Pp. viii+633. (Palo Alto, Calif.: Annual Reviews, Inc., and the American Physiological Society, 1958. On sale by Annual Reviews, Inc.) 7 dollars.

According to the preface in this twentieth "Annual Review of Physiology", the total number of articles of biological interest has increased during these twenty years from 77,000 to 145,000 a year, and the number of papers reviewed has increased during the same period from 4,256 to 5,543. The size of the volumes published has remained almost constant, and the number of words per paper has fallen. These figures show that the authors have been more selective than some people supposed, and present an awful picture of the amount of literature which a physiologist might study if he had the time—nearly four hundred papers a day.

The prefatory chapter is written this year by W. J. V. Osterhout, and gives an interesting summary of some of the fundamental work he has done on the physiology of aquatic animals since he first became interested in the subject sixty-six years ago. About half the remaining twenty articles deal with main branches of physiology—circulation, respiration, reproduction, digestion, excretion, temperature, and the central nervous systems, and provide new instalments of serial stories which are contained in each volume. There is a series of articles on different aspects of Russian physiology; last year Russian neurophysiology was discussed, this year cardiovascular aspects are considered, and next year we are promised an article on metabolism and endocrinology. Those who cannot read Russian are thus given an opportunity of finding out what they are missing. Comparative physiology is represented this year by an article on excretion; last year it was osmotic regulation and next year it will be blood pigments and biological clocks.

In addition to these standard subjects, there are various other articles of special interest this year. There are articles on growth by J. A. Russell and A. E. Wilhelmi, on the physiology of the skin by W. B. Shelley and R. P. Arthur, on synaptic transmission by W. D. M. Paton, on the hypothalamus, adenohypophysis and adrenal cortex by G. Sayers, E. S. Redgate and P. C. Royce, and many others by well-known authors.

The editors are to be congratulated on maintaining so high a standard. Some people think that this volume is little more than an uncritical reproduction of a card index; but some of these articles are much more than this and give a balanced picture of the best modern work. Anyone who hopes to keep in touch with a wide field of physiological work will derive benefit from this book. J. H. Gaddum

HORMONES IN BLOOD

Ciba Foundation Colloquia on Endocrinology

Vol. 11: Hormones in Blood. Edited by G. E. W. Wolstenholme and Elaine C. P. Millar. Pp. xii+416. (London: J. and A. Churchill, Ltd., 1957.) 56*s*. net.

Starling defined a hormone as a substance produced in one part of the body to be carried by the circulating blood to another part, where it elicited a physiologically important response. He believed hormones to play an important part in the mechanisms responsible for the co-ordination of function in the body, and time has emphasized the soundness of this belief. Since the time when Aschheim and Zondek found that the urine of pregnant women contained gonodotropic and œstrogenic substances, there have been got from all sorts of urine many materials which possess activity similar to that of extracts of endocrine glands; but, unfortunately, it has not always been remembered that the substance in urine is not necessarily that secreted by the endocrine gland. Moreover, chemists have synthesized substances, for example, diethylstilbœstrol, which, weight for weight, are more physiologically active than hormones when injected into animals or man. This fact has in some instances turned attention from natural hormones to cheap and easily obtained substitutes which may be of particular therapeutic value. The sub-title of the colloquium on which this book is based could have been "Back to Blood", since a study of the hormonally active substances in blood is likely to be more relevant to the problem of what is a hormone in terms of Starling's definition than the identity of active substances present in urine or solely the product of the chemist's ingenuity.

But, as often happens, a step nearer to the problem that can be formulated brings to light others that previously were not so clear.

In some instances, perhaps in many, the substance circulating in the blood is not identical with that which brings about a physiological effect in the tissues, that secreted by the endocrine gland being altered before entry into the tissues where it acts. Thus, Starling's definition may need extension and expansion; but definitions, valuable though they be, often make a cloak for ignorance. This volume is the record of a most thorough and illuminating discussion by experts of how interest has shifted from urine to blood, and is already beginning to move from blood into the tissues, where the processes involved in the control of metabolic functions actually take place. What is precisely meant by the word 'hormone' becomes less certain as a result, but the book conveys excellently the excitement of uncertainty in a rapidly developing and expanding field of research.

F. G. Young

An International Symposium on Aldosterone

Edited by Alex F. Muller and Cecilia M. O'Connor. Pp. x+232. (London: J. and A. Churchill, Ltd., 1958.) 40*s*. net.

IN June 1957, the Clinique Thérapeutique of the University of Geneva organized an international symposium on aldosterone. This book is a record of the papers given and the discussions which they produced. Aldosterone is one of the hormones of the adrenal cortex which is concerned in the regulation of the level of electrolytes, and its secretion appears to be influenced directly by changes in the water and electrolyte balance of the body. One of the main problems in the study of the functions of aldosterone is the difficulty of estimating it with reasonable accuracy in body fluids and tissues, and this question was discussed in the first part of the symposium. In other papers, the biological action of aldosterone was compared with that of other related hormones and work was described on the synthesis of aldosterone by tissues *in vitro*. The second day of the meeting was devoted mainly to the clinical and biochemical findings in patients with an abnormality in aldosterone secretion.

Some of the communications illustrate vividly what a lot of information on aldosterone has been obtained by the use of very small amounts of this scarce material. A particularly striking paper describes how aldosterone labelled with tritium was prepared by incubating correspondingly labelled progesterone with capsule strippings from ox adrenal glands, and how the resulting radioactive aldosterone was then used to study the metabolism of the hormone in the body.

Those interested in the steroid hormone field will be glad that the proceedings of this symposium have been made available in book form, especially as much of the experimental work appears here in print for the first time. It would have been helpful if a figure had been included, showing the structural relationships between the various steroid hormones discussed. All the papers and discussions are in English.

D. C. HARRISON

Guide to Unpublished Research Materials

Lectures delivered at a Vacation Course of the University of London School of Librarianship and Archives in April 1956. Edited by Ronald Staveley. Pp. vii+141. (London: Library Association, 1957.) 21*s*. (15*s*. to L.A. members.)

THIS volume, which is complementary to an earlier publication in 1952, "Government Information and the Research Worker", is intended to assist the staff of research libraries and others who collect and use the records of research. The lectures are arranged in two parts. In the first, dealing with science and technology, Mr. A. H. Holloway contributes an introductory chapter on the research report, in which, although the problems of such reports, including the secrecy aspect, when emanating from Government sources are fairly presented, the industrial aspects are largely ignored; nor are they adequately discussed in the following review of materials and sources of the United Kingdom by J. C. Malloch and R. J. Brierley. Mr. A. N. Holloway deals with the research report in North America, while Dr. A. L. Mackay's account of materials and sources of Eastern Europe and China relates largely to published as well as to unpublished sources. A paper by E. J. Offord on the United Kingdom's participation in European Technical Information Projects replaces that delivered in the course.

The remaining seven lectures deal with the social services. Miss Barbara Kyle discusses bibliographical control of unpublished material; L. T. Williams, statistical material and sources; T. Carter, sources in market research; B. D. Copland, the advertising agency and the interchange of information; R. O. Godwin, market research in industrial fields; W. L. Guttsman, who draws largely on published sources, with materials and sources in sociology; and C. M. Franks, with materials and sources in psychology.

From the factual point of view the volume should achieve its purpose and it directs attention to the new function of the Technical Information and Documents Units of the Department of Scientific and Industrial Research as the national centre for receipt of unpublished research materials from other members of the Organization for European Economic Co-operation. Nevertheless, the value of the volume would have been enhanced by a more critical and forward-looking approach to the character of unpublished material. Generally speaking, the adequacy of existing methods of publishing and handling information is accepted without questioning their appropriateness to the needs of the research worker, or to modern techniques of handling and distributing information.

R. BRIGHTMAN

Elements of Partial Differential Equations

By Prof. Ian N. Sneddon. (International Series in Pure and Applied Mathematics.) Pp. ix+327. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 56*s*. 6*d*.

THIS is essentially a user's book; its main aim is to provide an account of methods whereby special solutions of the famous equations of classical mathematical physics may be derived, and to connect these solutions with physical problems. A good honours student with an interest in applied mathematics should find the book to his taste, and easy to read.

An introductory chapter deals with ordinary differential equations in two or more independent variables; the account of Pfaffian forms is excellently illustrated by Carathéodory's formulation of the basic principles of thermodynamics. The simpler classical processes for the solution of partial differential equations, such as those of Charpit and Jacobi, are discussed in the second chapter, and in the third a survey of second-order equations is given. The remaining three chapters attack the central theme of the book: Laplace's equation, the wave equation, the diffusion equation. Considerable emphasis is laid on the use of Green's function; the treatment is elementary but forward-looking, and should encourage the student to make a deeper study of the connexion with integral equations and integral transforms, a connexion which Prof. Sneddon insists on frequently but cannot pursue in great detail in an elementary account. Pains have been taken to bring in such modern methods as can be explained in reasonably simple terms; fundamental theory is carefully explained, and key theorems are either proved in full, or the need for such proof pointed out and references given.

Physical problems are used to introduce the appropriate equations, to illustrate the theory, to provide worked examples and to furnish a respectable but not overwhelming number of exercises for the student.

T. A. A. BROADBENT

PEACEFUL USES OF ATOMIC ENERGY

UNITED NATIONS CONFERENCE AT GENEVA

THE second United Nations Conference on the Peaceful Uses of Atomic Energy far outstripped the first Conference in the number of papers presented and the number of participants. The scope of the Conference was widened by the inclusion of six 3-hr. sessions on controlled fusion research, and this provided some of the most stimulating new information at the Conference. The discussion of this subject was greatly helped by the final stage of declassification of this field of research by the United States and the United Kingdom. The U.S.S.R. presented to the Conference four volumes containing one hundred papers describing the results of their fusion research up to the present time, and also gave some information about their recently completed large-scale fusion devices. New sessions were included on the separation of isotopes by diffusion plants and centrifuges and other methods, but the continued classification of diffusion plant technology reduced the scope of discussion in this field.

An outstandingly successful scientific exhibition was held in a specially built prefabricated building in the grounds of the Palais des Nations. The United States showed at least ten working fusion experiments from Livermore, Los Alamos, Oak Ridge and Princeton, and this was immensely valuable in enabling scientists to grasp the principles of the many different approaches to controlled fusion. The principles of construction and operation of reactors were equally well shown. The U.S.S.R. showed models and photographs of their latest fusion devices, their nuclear propelled icebreaker and their power stations in construction. The French showed models ranging from their pilot diffusion plant to their nearly completed propane bubble chamber for working in high-energy physics. The United Kingdom exhibition was modest in size compared with the United States exhibition but high in quality. It included a one-third scale model of ZETA, a working model of a 'fast pinch' fusion experiment from the Atomic Weapons Research Establishment, a wide range of scientific exhibits, and models illustrating new reactor developments.

A large industrial exhibition was organized in the city, and eighty-four British firms contributed a very impressive range of exhibits.

Many new scientific films were shown at the Conference, including films describing applications of radioisotopes in the United Kingdom; the United States and U.S.S.R. programmes of controlled fusion research; and the first full-scale 100-MW.(E) nuclear power station to operate in the U.S.S.R. This power station has been built together with a new town on some undisclosed site in Siberia. It is ultimately to have six similar units.

Sessions on nuclear power described the operating experience acquired during the past three years on the prototype power stations, Calder Hall and Shippingport, and the progress which is being made in the construction of the world's first nine full-scale nuclear power stations. These are of five main types —the U.S.S.R. graphite-moderated water-cooled reactor, the United Kingdom graphite-moderated gas-cooled reactor, the United States pressurized and boiling-water reactors and the United States 100 MW.(E) fast reactor. The boiling-water reactor is growing in favour owing to the success of the United States experiments. Its capital cost seems likely to be 30 per cent below the cost of the pressurized water reactor power stations.

The Canadians and the Czechs are developing the heavy-water-moderated reactor cooled either by steam or gas or heavy water. The Canadians believe that they can use fuel of natural uranium oxide and achieve fuel costs of about one mil.

The economic sessions showed that the date at which nuclear power costs are expected to achieve parity with conventional power costs ranges from 1962 in the United Kingdom—for the 500 MW. station remote from coalfields—to 1972 or thereabouts in the United States, where nuclear power has to compete with cheap hydro power and low fossil-fuel costs in many areas. Nevertheless, it appears that 15,000 MW. of nuclear power capacity will be installed by 1965–70. In the group of 'underdeveloped countries', India and Japan will take the lead and expect to have 500 and 750 MW. installed, respectively, by 1965.

Descriptions were given of the more advanced types of nuclear power stations which have reached the reactor experiment stage. The reactor using an organic liquid as a moderator is showing promise as a simple low-pressure system with potential application to propulsion and small power units. The aqueous homogeneous liquid uranium salt fuelled reactor of Oak Ridge has had troubles due to failure of welds in the inner core vessel and has now some difficulty with the stability of the liquid fuel. The graphite-moderated sodium-cooled reactor experiment is providing experience in liquid-sodium technology as well as experience in operating metallic fuel elements at higher temperatures than have been used hitherto. The United Kingdom reported on the next stage of development of the United Kingdom power reactors. The advanced gas-cooled reactor, which is being built to operate at fuel element temperatures of 600° C. using uranium oxide fuel, was discussed. The next stage, the high-temperature gas-cooled reactor project, aiming to use all-ceramic elements and to produce outlet gas temperatures of 700° C., was also described. This reactor experiment may be built at Winfrith Heath as an Organization for European Economic Co-operation project. Experiments on the stability and physics of the fast reactor and the construction of a full-scale 100 MW.(E) fast reactor in the United States and plans for fast reactors of 50 MW. and 250 MW. output in the U.S.S.R. were described.

The Conference received reports on the first semi-commercial nuclear propelled ships. The United States *Savannah*, coming into commission in 1960, will use a pressurized water reactor developing 22,000 shaft horse-power. It will carry up to a hundred passengers and is estimated to cost 30 million dollars, so it is far from being economic. The United States expect also by 1962 to install a boiling-water reactor in a tanker in the hope of reducing capital costs of the propulsion unit to a figure nearer parity with conventional units.

The U.S.S.R. reported on their icebreaker *Lenin*, which will come into commission in 1959. This will have three pressurized water reactors, one stand-by, and 44,000 shaft horse-power will be developed. This icebreaker will open up a 6,000 mile seaway north of the U.S.S.R., an application which would be impossible without nuclear power.

The controlled fusion sessions and the exhibition dealt with experimental devices falling into two main classes. The first class use the pinch effect to confine a hot conducting deuterium plasma in a toroidal or straight tube. Heating is carried out by resistive heating, shock-wave or compression heating, and radio-frequency heating. Under some conditions—when high electric fields are used to maintain the current—large bursts of 5-kV. X-rays were observed, believed to be due to runaway electrons. This produces a serious loss of energy in the plasma. Ion temperatures of several million degrees were reported with electron temperatures much lower. The maintenance of stability and containment of the hot plasma as energy input is increased is the crucial question for the future development of this class of fusion devices.

The U.S.S.R. reported that they had recently completed ALPHA—very similar in size and appearance to ZETA—in a Leningrad laboratory.

The second class of devices is the 'Mirror Machine', in which the hot plasma is also contained by magnetic fields. In one of these devices, the D.C.X., the hot plasma is formed by injecting 600-kV. molecular ions, and stripping them into atomic ions and neutral atoms in an intensely powerful carbon arc. The neutral atoms leave the chamber and the atomic ions are trapped by the magnetic field and convey their energy to the plasma. The U.S.S.R. have a giant version of this just complete, which they call OGRA. In OGRA the molecular ions spiral in a long path to and fro between magnetic mirrors, and it is hoped that they will be dissociated by impact with neutral atoms. The original mirror machine, the pyrotron, heats the plasma by compressing it with magnetic fields—working like magnetic pistons. A delightful small mirror machine from Los Alamos, SCYLLA, compresses a plasma by a very short pulse magnetic field, produced by a condenser discharge in a fraction of a microsecond. The machine was working in the exhibition, producing pulses of neutrons, activating silver foils the subsequent decay of which the admiring crowds could follow.

In a variant of the mirror machine from Berkeley, ASTRON, amperes of multi-million volt electrons are to be injected into a chamber and constrained to follow a path which will produce, by a combination of their magnetic fields with the external field, a stable 'magnetic bottle' which it is hoped will enable a high-temperature plasma to be formed by electron collisions.

The mirror machines, like the pinch machines, will depend for their success on maintaining the tenuous plasma, generating perhaps hundreds of megawatts per cubic metre in a relatively quiescent state. The energy generated may be of the same order as in fission reactors, but instability time constants could be many orders of magnitude smaller.

So far, although lots of fusion neutrons have been produced by these devices, no laboratory has claimed that they are true thermonuclear neutrons. Ion temperatures of several million degrees have been reported, with electron temperatures much lower for some of the pinch machines. Mirror machines have produced electron temperatures of ten million degrees, but ion temperatures are so far unknown. The true thermonuclear neutrons are evidently 'just around the corner', but it is probably a long haul from them to reach the break-even point when energy output from the plasma equals the energy input. Thermonuclear power stations seem at least twenty years away, but the subject has excited such intense interest and experimental activity that predictions based on present knowledge may soon be out-dated.

The biological sessions were well attended, and the material presented was much newer and fresher than in the 1955 Conference when ten years of work was reported. One of the most interesting reports came from the Oak Ridge Laboratory, on the radiation-induced mutation-rate in mice. Hitherto the direct proportionality of gene mutation with dose of radiation has been accepted as a law which holds, irrespective of dose-rates, down to the lowest accumulated doses. W. and L. B. Russell produced evidence for departure from linearity in the relation between mutation-rate and dose for point mutations in the spermatogonia of male mice. Furthermore, they showed that the mature egg cell of female mice is substantially less sensitive to the induction of mutations than the spermatogonia of the male. Similar results have recently been reported by Carter from Harwell. These two facts will probably necessitate a complete reconsideration of the quantitative predictions of the genetic hazard.

The rapidly expanding application of radioisotopes was shown in eight sessions. At the 1955 Conference, Glascock pointed out the potential importance of tritium as a label to supplement the use of carbon-14. This was borne out by a description in this second Conference of the incorporation of tritium into thymidine in order to build a specific label into the nucleoproteins of cell nuclei. Tritium with its very low-energy beta-emission allows very precise localization by the autoradiographic technique. Already this is providing direct evidence on cell nuclear processes which formerly were merely inferred from indirect considerations.

Clinical medicine benefits in the same way from the application of radioactive tracers to problems of diagnosis and the measurement of individual body-functions. The physician is no longer limited to identification of what goes in and what is excreted; he can trace intermediary metabolism *in vivo* by direct counting or by sampling tissues or body fluids. A notable contribution to the Conference was the increasing accent on the use of shorter-lived radioactive isotopes in order to reduce the radiological dose to the subject. Ingenious, too, was the application of oxygen-15, produced in a cyclotron, for investigating malfunction of the lung. The isotope pill for diagnostic purposes predicted by Dr. Libby was demonstrated in the exhibition.

The industrial uses of radioisotopes continue to increase rapidly. The applications to industrial chemistry are among the most important new fields. Sources of radiocobalt in strengths of the order of 100,000 c. will soon be available and will be followed by radiocæsium extracted from atomic wastes. Promising applications to the production of graft polymers, vulcanization, sterilization and food preservation were described and illustrated in the exhibition. Radioactive catalysts were reported to increase yields several fold.

The sessions on fundamental research were instructive and entertaining. The Dubno 12-GeV. accelerator and the Saclay 3-BeV. accelerator were described. Cosmic ray workers flying large stacks of photographic emulsions in Comet proving trials have been able to obtain an enormous amount of new data on the collision of protons ten thousand times more energetic than any which can be produced by the largest planned accelerators. The demonstration, by the orbiting satellites, of the existence of intense belts of 40 MeV. protons, a thousand kilometres or so above the Earth in particular latitudes, was also described. The great question of why pions and nucleons exist with their particular masses and particular interactions was said to remain totally unanswered, in spite of the wealth of new knowledge produced by the accelerators. Dr. Feynman gave an entertaining account of the strange particles, which now total thirty-one. The theoreticians have a new occupation of inventing new rules and waiting to see whether the latest strange particle obeys them.

In the field of nuclear data the present situation leaves no room for complacency, since present reactor technology requires much more precise information which we shall have to work hard to obtain. To help in this, important new tools such as the Harwell linear accelerator and neutron booster providing enormously powerful pulses of neutrons are becoming available.

In the chemical sessions an account was given of the isolation of weighable amounts of berkelium; chemists look forward to going well beyond element 102, aided by expensive reactors with neutron fluxes up to 10^{16} per cm.^{2} per second. The chemical effects of fission fragments appear to be much higher than anticipated, and this may have important technological consequences. There has been a rapid advance in solvent-extraction technology, and long-chain amines and long-chain derivatives of phosphoric acid have been synthesized with highly specific activities.

A great deal of new and valuable information was obtained at this Conference, not only from the lectures but also from the exhibition and films, which made it possible to see in a few days, in an exciting visual way, work proceeding throughout the world. The Conference provided the opportunity for innumerable discussions in small groups to supplement the work of the formal sessions. Future accelerators, the future of modern physics, genetics, plasma physics throughout the world, the future of co-operation in atomic energy in the Commonwealth, in Europe and in the world, and numerous other topics were discussed. The very rich feast taxed our physical and mental endurance.

There has been much informal debate as to whether there should, in three or four years time, be another conference on this scale or larger. On one hand, it was argued that only by having a conference of such wide scope can one persuade Governments to provide the finances for the immensely rewarding exhibitions and to release new information, and also persuade individuals to write up their research in a form suitable for presentation to the world. It was generally agreed that much cross-fertilization between the different ramifications of atomic energy resulted. All this is true enough and we will need to balance this against the great effort and interruption of research work required to prepare for these conferences. After a few months of thinking over the result, we may be better able to decide.

We are, however, all sure that the Conference was immensely worth while. J. D. COCKCROFT

AIR SHOWERS OF SIZE GREATER THAN 10^5 PARTICLES

(I) CORE LOCATION AND SHOWER SIZE DETERMINATION

By M. H. BRENNAN*, D. D. MILLAR and C. S. WALLACE

The F.B.S. Falkiner Nuclear Research and Adolph Basser Computing Laboratories,
School of Physics†, University of Sydney

CURRENT observations on the extensive air showers of cosmic rays[1,2] are concerned with two main problems. In the first of these, the cosmological problem, observations are made in order to determine what anisotropies may exist in the directions of incidence of the high-energy primary particles which initiate the showers, and whether there exists a high-energy cut-off in the energy spectrum of these primaries. Such observations have led to the development of large-area detectors of air showers in order that giant air showers, corresponding to primary energies greater than 10^{16} eV., may be detected with appreciable frequency. The second problem is the investigation of the high-energy nucleon–nucleus interactions of the primary and secondary nuclear-active particles in the air, interactions which give rise to the development of the air shower detectable in the lower atmosphere, and here may be considered showers of a more modest size, detectable with sufficiently high frequency with arrays of smaller dimensions.

In order to provide information on the second of these topics, observations were commenced in Sydney at the beginning of 1957 on the properties of showers of size 10^5 particles and greater. Because of the dimensions of the apparatus and of the range of particle densities which can be measured by the detectors, and also because of the rapid decrease of the frequency of showers with increasing size, these

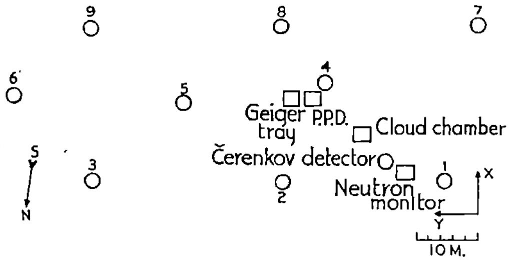

Fig. 1. Plan view of air-shower array. The circles numbered 1–9 represent the liquid scintillation counters. The triggering Geiger trays (not shown) are grouped around the cloud chamber

observations cover an effective range of shower sizes from 10^5 particles to 10^7 particles. Several different instruments are used for detecting the various types of particles in the air showers, for measuring their local density and in some instances for providing information on their directions. These instruments include a large Wilson cloud chamber, an unshielded tray of Geiger counters, a detector of penetrating particles consisting of an array of hodoscoped Geiger counters in a lead pile, a multi-element atmospheric Čerenkov detector, and a device for registering the counts given by a neutron monitor in the period immediately following a shower.

To be able to interpret the results obtained from these instruments, in terms of the structure and development of the shower, it is necessary to know the size of the shower, and the position of its core and the direction of arrival relative to the c ting instruments.

This article describes the array of dete s, the recording gear, the calculations used to in the first two of these quantities, and gives so details of the performance and accuracy of th ystem. The determination of the shower directio will be dealt with more fully in a later publicati

The Array of Detectors

For reasons of cost and convenience, th paratus has been placed on the roof of the U rsity of Sydney School of Physics, and on thre telegraph poles adjacent to the building. The array comprises nine liquid scintillation counters, each of 0·23 m.^{2} sensitive area and 10 cm. depth, arranged in a rather irregular manner, dictated by the topography of the site, inside a rectangle 70 m. × 30 m. The counters are about 20 m. apart (Fig. 1).

These counters are used for giving a measure of the density of the air shower particle flux, by giving an electrical pulse the height of which is proportional to the number of electrons traversing the counter. Some details of their response to the air shower flux have been described elsewhere[3]. As well as the nine density measurements provided by these counters, the time of arrival of the particles is measured in four of the counters, numbers 2, 3, 8 and 9. The difference in these times is used for determining the plane of the shower front, and hence, the direction of the shower axis[4].

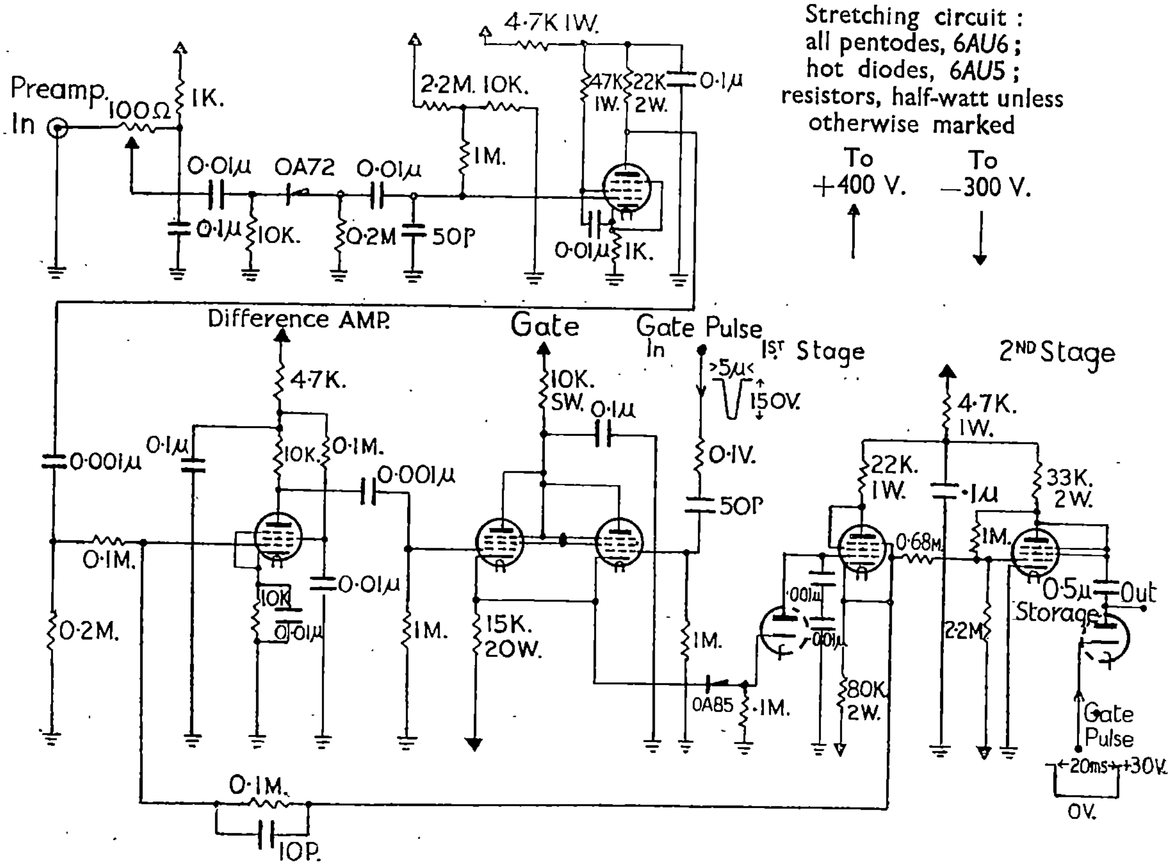

Fig. 2. Stretching circuit used for recording pulse-heights from scintillation counters

Recording the Results

The fast pulses carrying the time-of-arrival information are presented sequentially on the trace of a high-speed oscilloscope, which is photographed. A full description of the details and performance of this gear will be given in another paper.

The pulses carrying the density-of-particles information from the nine scintillation counters are pre-amplified and transmitted via coaxial cable to a central recording station. Here they are further amplified, and gated in coincidence with a master pulse generated whenever a shower triggers the recording gear. The details of the triggering system are described later. The resolution time of the gate is about 5 μsec. The gated pulses are then used to charge up condensers to voltages equal to the heights of the pulses. These condensers have a polystyrene dielectric, and will retain their charge for a period of hours without appreciable leakage. A diagram of the circuit used is given in Fig. 2.

The pulses produced by some of the associated equipment, for example, the multi-element Čerenkov detector and the unshielded Geiger tray, are stored in the same manner.

These stored voltage-levels are then converted one at a time into a binary number in the range 0–40. This covers a voltage range 0–60 V. by 1-V. steps in the range 0–20 V., and by 2-V. steps in the range 20–60 V. The gains of the circuits are arranged so that 1 V. corresponds to the mean pulse size caused by a single relativistic vertical μ-meson traversing the scintillation counter. This level of 1 V. is taken to represent one 'scintillator particle'[3]. The binary numbers thus formed are automatically punched out one at a time on standard 5-hole teleprinter tape. Also included on the tape are binary numbers representing the time of arrival of the shower as day of the week, hour and minute, and a serial number for the shower.

Some of the associated instruments, such as the penetrating-particle detector and the neutron-monitor register, give information directly in 'yes–no' form. This information is stored on thyratrons and punched sequentially on the tape.

The recording of the results from a single shower requires about 2 ft. of tape, and the automatic punching of this tape takes about five minutes. The output tape is allowed to accumulate for a day, during which some sixty or so events will have been recorded. The tape is then fed into the SILLIAC Digital Computer in the Adolph Basser Computing Laboratory for decoding and analysis. A simplified block diagram of the recording gear is given in Fig. 3.

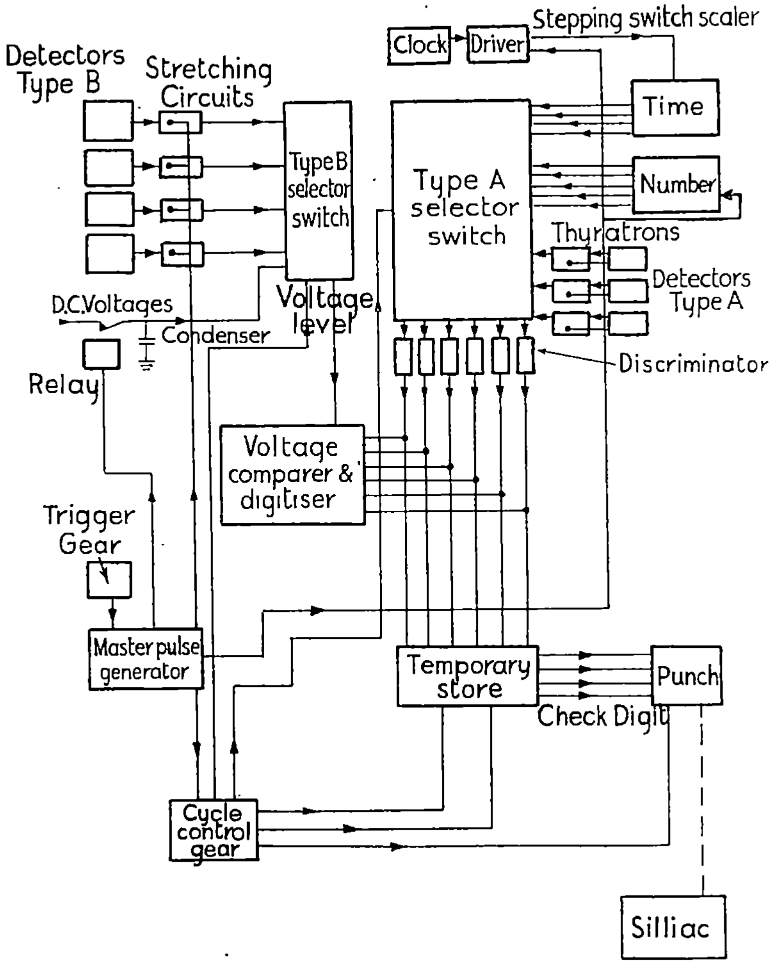

Fig. 3. Block diagram of recording gear

Analysis of the Data

The data tape is input to SILLIAC with a programme which converts recorded pulse-heights into numbers of particles traversing the detector according to the gains of the scintillation counters, which are measured daily by measuring the counting rate of pulses above the supposed 'one scintillator particle' level. An output tape is then obtained which, when printed on a teleprinter, gives a convenient visual presentation of the recorded events. No allowance is made in the programme for variations in the gain of the stretching circuits, which are set fortnightly, and remain constant within about 5 per cent. Also included on the output tape is the direction of arrival of the shower, as determined from the time delays. These delays are input via a manually punched tape.

This output tape contains the results from the various special detectors, besides the particle density information required to determine the core position and size of the shower. This additional information is carried without alteration through the next, and main, stage of the analysis, in which the core position and size are determined.

The analysis is carried out by fitting an assumed lateral structure function for the shower to the observed numbers of particles in the scintillation counters, and varying the assumed centre and total size of this structure function until the 'best' fit is obtained. It is assumed that the shower axis cuts the observation plane at a point (X, Y) and that the shower contains N electrons. We then expect to see a number m_i of electrons in a counter situated at $(x_i y_i)$, $(i = 1, 2 \ldots 9)$; where

$$m_i = N f_i$$

and

$$f_i = 0{\cdot}23 \frac{1}{2\pi} [\exp - r_i/75]/75(r_i + 1)$$

0·23 is the area of each counter in square metres, and r_i is the distance in metres from the counter to the shower axis, and is given by:

$$r_i^2 = (X - x_i)^2 + (Y - y_i)^2 - [l(X - x_i) + m(Y - y_i)]^2$$

where l and m are the direction cosines of the shower axis in the X and Y directions.

The form of the structure function, f, assumed by us is essentially identical with that used by the air shower group at the Massachusetts Institute of Technology[5]. However, we take a fixed characteristic radius of 75 m. and remove the singularity at the origin by using the divisor $75(r_i + 1)$ rather than $r_i r_0$.

We compute the probability that we would see a number of particles n_i when we expect to see a number m_i. The product of these probabilities (assumed to be Poissonian) for the nine counters is then the probability that a shower of the assumed type S characterized by X, Y and N would give rise to an event of the observed type E, characterized by $\{n_i\}$, and may be written $P(E/S)$. We fit the observed event by maximizing the posterior probability $P(S/E)$ that an event E was caused by a shower of type S, where:

$$P(S/E) = P(E/S)\, P(S)/P(E)$$

(The use of the posterior probability is discussed further in the appendix by one of us (C. S. W.).)

$P(S)$ is the *a priori* probability of occurrence of a shower of type S, taken to be proportional to $N^{-2{\cdot}5}$.

$P(E)$ is the *a priori* probability of recording an event of type E. Since $P(E)$ is independent of X, Y and N, it is neglected in the calculation.

We actually compute and minimize the function:

$$F(X,Y,N) = -\log_e (P(E/S) N^{-2{\cdot}5})$$

We take:

$$F(X,Y,N) = 2{\cdot}5 \log_e N + \sum_i [-\log_e (e^{-m_i} m_i^{n_i}/n\,!)]$$

Writing $m_i = N f_i$,

$$F(X,Y,N) = N \sum_i f_i - \sum_i n_i \log f_i - (\sum_i n_i - 2{\cdot}5) \log N + \sum_i \log n_i\,!$$

Since the recording system can deal only with numbers of particles up to 60, if $n_i = 60$, we use, instead of the probability of getting exactly 60 particles, the probability of getting 60 or more particles, that is

$$\sum_{n=60}^{\infty} (\exp - m_i)\, m_i^n/n\,!$$

We have tabulated $R(m_i)$ defined as:

$$-\log_e \sum_{n=60} (\exp - m_i)\, m_i^n/n\,!$$

for $m_i = 0, 1, \ldots 80$.

Reserving the subscript i for unsaturated counters $(n_i < 60)$ and using j for saturated counters, we have:

$$F(X,Y,N) = N\sum_i f_i - \sum_i n_i \log f_i - (\sum_i n_i - 2{\cdot}5) \log N + \sum_j R\,(N f_j) + \sum_i \log n_i\,!$$

To find the values of X, Y, N leading to a minimum for $F(X,Y,N)$, we first define $F_0(X,Y)$ as the minimum value of $F(X,Y,N)$ obtained for fixed X, Y by varying N. When there are no saturated counters, the value $N_0(X,Y)$ for N which gives this minimum is simply:

$$N_0 = [(\sum_i n_i) - 2{\cdot}5]/\sum_i f_i$$

Where one or more counters are saturated, we first compute a series of approximations to N_0, which are:

$$\frac{\Sigma n_i - 2{\cdot}5}{\Sigma f_i}, \frac{\Sigma n_i - 2{\cdot}5 + 60}{\Sigma f_i + f_a}, \frac{\Sigma n_i - 2{\cdot}5 + 120}{\Sigma f_i + f_a + f_b}, \ldots,$$

where $f_a, f_b, \ldots$ are $\{f_j\}$ arranged in increasing order of magnitude. In doing so we are in effect ignoring first all saturated counters, then all but the one with the least expected number, then all but the two with the least expected numbers, etc.

The largest of these approximations, which must all be less than N_0, is used as the starting value for a Newton's method approximation to the solution of the equation:

$$\frac{\partial}{\partial N} F\,(X, Y, N) = 0$$

The solution of this equation is obtained to about 1 per cent accuracy.

The minimum value of $F_0(X,Y)$ is then found by varying X and Y by a method of steepest descent, taking as initial values for X and Y the co-ordinates of the counter having the largest value of n_i. The best values X_0, Y_0, N_0 (X_0, Y_0) are then printed, together with $F(X_0, Y_0, N_0)$ and estimates of the positive and negative errors in X, Y and N.

These errors are based on the sharpness of the minimum of $F_0(X,Y)$, and are such that the range of values for X, Y and N specified by these errors includes all sets of values (X_1, Y_1, N_1) in the neighbourhood of (X_0, Y_0, N_0) which are more than one-eighth as probable as (X_0, Y_0, N_0). The finite width of the minimum about $F_0(X,Y)$ with variation of N is neglected, as it is always much smaller than the errors in N defined above. Other calculations referred to below have shown that values of X, Y and N in the ranges specified usually contribute at least 90 per cent of the total contribution to the integral:

$$\int_{-\infty}^{\infty} dx \int_{-\infty}^{\infty} dy \int_{0}^{\infty} dN\, P(S/E)$$

To give a convenient measure of how well this calculated shower fits the observed event, we also compute and print a quantity χ^2 defined by:

$$(s - 3)\chi^2 = [\sum_i (n_i - m_i)^2/n_i]_{0 < n_i < 60} + 2[\sum_i m_i]_{n_i = 0} + [\sum_j 60/m_j]_{n_j \geqslant 60}$$

where s is the number of counters in use, and m_i, m_j are calculated from X_0, Y_0, N_0. The quantity χ^2 is

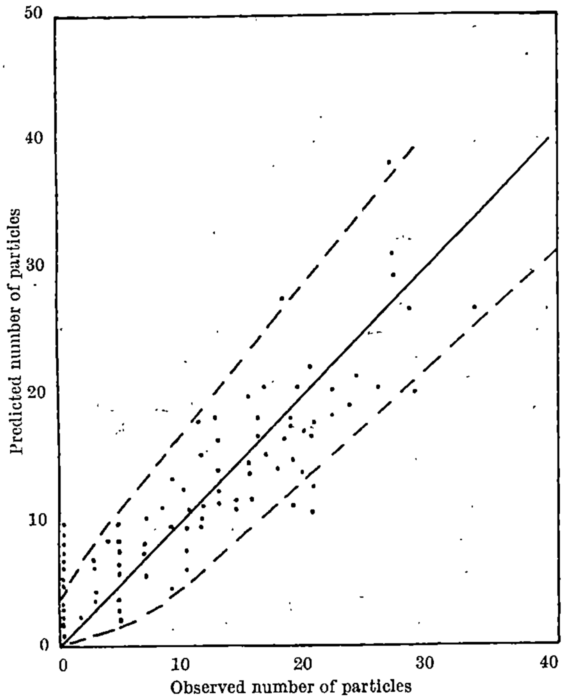

Fig. 4. Scatter diagram showing correlation between predicted and observed numbers of particles in a scintillation counter in the air-shower array. The co-ordinates of each point show the predicted and observed numbers for one shower. The dotted lines represent the 10 per cent limits of a Poissonian distribution

a more convenient measure of fit than $F(X_0Y_0N_0)$ for purposes of comparison with other events, because it has an expectation value of approximately one.

The complete analysis process described above takes about 45 sec. per event.

Accuracy of System

The gains of the scintillation counters are fixed by daily adjustment to an accuracy of about 5 per cent. The pulse storage and digital conversion circuits are calibrated to 5 per cent fortnightly. We therefore expect the particle density measurements to be limited to about 10 per cent accuracy by the instrumentation. This is, however, smaller than the expected Poissonian fluctuations in the measured density. Since we were not sure what effect these fluctuations and instrumental errors would have on the determination of the core position and size of the showers, the following check was carried out: a typical batch of events was analysed as if one of the scintillation counters were unserviceable, that is, the observed number of particles in it was not used in analysing the events. Then, the expected number of particles through this counter was computed from the estimated core position and shower size, and compared with the observed number. The results of this comparison are shown in Fig. 4. It can be seen that the agreement is in general within the expected statistical fluctuations.

The 'errors' in core location and shower size estimated by the analysis programme (see earlier) vary widely from shower to shower. For a shower of size 10^6 particles falling inside the array, the location errors are normally about 5 m., and the errors in size about 20 per cent in the positive direction and 10 per cent in the negative direction.

Separate calculations (discussed in the appendix have been made to obtain the probability distribution for N independently of X and Y. These distributions normally have a peak at a value of N about 5 per cent greater than N_0, and are quite skew, having a median value about 15 per cent greater than N_0. This skewness increases when the showers fall outside the array.

Similarly, for 10^6 particle showers falling within the array, the probability distribution of (X,Y) independently of N has 90 per cent of its total probability within 5 m. of (X_0,Y_0); but when the shower falls outside the array, the distribution has a tail extending away from the array, and the core location errors for such showers, and for small showers within the array, may frequently be 15 or 20 m.

Lateral Structure Function

While this array was not designed to investigate the lateral structure of showers, we have obtained from our results an average structure function for showers of sizes in the range 10^5–10^7 particles, mainly as a check on the validity of the function which we, together with the Massachusetts Institute of Technology group, assume in our calculations, namely:

$$\rho(r) = \frac{N}{2\pi}\,\frac{\exp(-r/r_0)}{r/r_0}$$

Although our observed distribution is based on a method of core location which assumes a lateral distribution, we have found that the core location of showers, for showers falling inside the array, is not very sensitive to the assumed distribution.

The distribution obtained is shown in Fig. 5, together with the above function and the theoretical distributions of Moliere and Nishimura and Kamata.

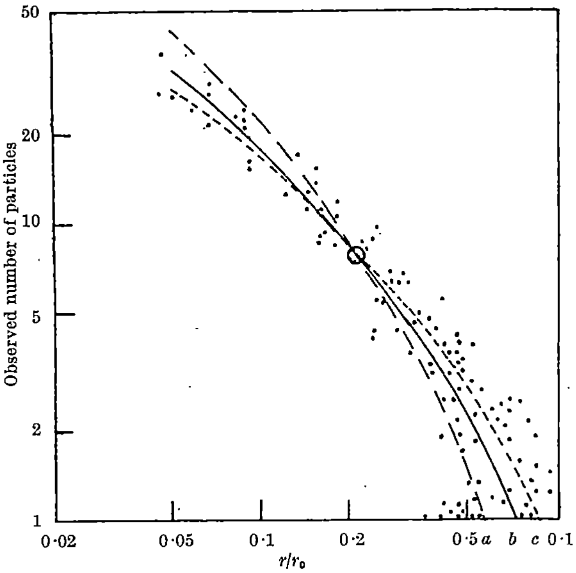

Fig. 5. Scatter diagram showing observed lateral structure function. The co-ordinates of each point represent the distance of a counter from the core of a shower, and the observed number of particles in the counter, normalized to a shower size of 3×10^6 particles. Points are plotted for every counter for 15 showers of sizes in the range 3×10^5 to 10^6 particles. Curve b is the structure function used in our analysis, curve a is the Moliere distribution and curve c is the Nishimura and Kamata distribution for $s = 1{\cdot}4$. Curve b is for a shower size 3×10^6 particles. The other two are normalized to it at the circled point

It can be seen that the agreement with our assumed function is quite good.

As has been found by other workers, the Nishimura and Kamata curve for $s = 1{\cdot}4$ fits the observed distribution very well, but there is a marked disagreement with the Moliere distribution.

Observed Rate of Air Showers

Because this array is primarily intended for the study of individual showers, the arrangements for triggering the recording gear have been designed to give the maximum rate of events likely to give a useful response in the special instruments attached to the array. The array may be triggered either by a four-fold coincidence of one or more particles in each of scintillation counters 2, 3, 8 and 9, or by a three-fold coincidence of more than five Geiger counters firing in each of three trays of 10 counters placed near the cloud chamber (Fig. 1). The area of each counter is 0·02 sq. m. Furthermore, no event is analysed unless at least three of the nine scintillation counters have recorded at least two particles, and no event is analysed if more than six of the nine counters are saturated.

Thus the question of what percentage of showers of various sizes falling in various positions will trigger the array and ultimately be analysed would be very difficult to answer, and we have made no attempt to do so. We therefore cannot obtain information about the rate of occurrence of showers from the majority of our recorded events, and so the rates we have determined have been based on rather poor statistics. However, we have calculated that any shower of size greater than 3×10^5 particles falling inside an area 20 m. × 28 m. centred within the area bounded by three triggering scintillators (at a time when the fourth was not in use) has a probability greater than 95 per cent of triggering the array. During a run of total sensitive time 115 hr., during which the Geiger-tray triggering was disconnected, some 59 showers of size greater than 3×10^5 particles fell in this area. The rate of showers of various sizes was consistent with an integral size spectrum given by:

$$K(> N) = 4{\cdot}5 \times 10^{-8} (N/10^6)^{-1{\cdot}6 \pm 0{\cdot}1} \text{ m.}^{-2} \text{ sec.}^{-1}$$

A further run using all four triggering scintillators in four-fold coincidence was made. Because of the more stringent triggering requirements, the collecting area for a probability of more than 95 per cent triggering was reduced to 13 m. × 16 m. for showers of size greater than 4×10^5 particles. Since this area was too small to yield many large showers, a further area (enclosing the first) of 25 m. × 31 m. was used for showers larger than 7×10^5 particles. Thirty-four showers were recorded in a sensitive time of 87 hr. The results from this run, when combined with the previous results, give a spectrum:

$$K(> N) = (4{\cdot}0 \pm 0{\cdot}5) \times 10^{-8} (N/10^6)^{-1{\cdot}7 \pm 0{\cdot}1} \text{ m.}^{-2} \text{ sec.}^{-1}$$

This spectrum is in substantial agreement with that obtained by other workers.

The sizes of the showers have been corrected in this to the sizes which would have been obtained by using Geiger counter detectors rather than scintillation counters. The details of this correction will be discussed in a later article.

Summary

The detecting array which has been described, together with the analysis of the observations based on the maximum likelihood method, provides a system for detecting and analysing air showers of size in the range 10^5–10^7 particles. The cores of such showers falling within the array may be located with an accuracy of ± 5 m., at a probability-level of 90 per cent, and their sizes determined within limits of + 20 and − 10 per cent at the same probability-level. If it were desired to increase the accuracy of these determinations, then it would be necessary to increase the areas of individual detectors so that the percentage fluctuations in numbers of particles traversing the counters might be reduced. It would be necessary at the same time to increase the accuracy of recording these numbers in order to keep instrumental uncertainties below the level of these reduced statistical fluctuations. In the same way, obviously, an increase in the number of detectors in use would also improve the accuracy of the system, but so far no quantitative estimate of the importance of these factors has been investigated.

With the existing arrangement a number of checks on the performance have been possible. Such a check is provided by the comparison between the predicted and the observed densities of particles at the position of one of the detectors, while others are afforded by the agreement between the shower structure function and the shower size spectrum as here reported and the determinations of these by other workers.

We wish to acknowledge the facilities made available for this work by Prof. H. Messel, and the invaluable support given by the Nuclear Research Foundation. Our thanks are also due to the other members of the Sydney Air Shower Group, Messrs. W. Layson, J. A. Lehane, J. Malos, P. C. Poole, M. H. Rathgeber and G. Winterton, for their assistance and co-operation.

One of us (M. H. B.) has been supported in this work by a grant from the General Motors–Holden Co., and another (C. S. W.) by a grant from the Australian Atomic Energy Commission.

Appendix: Use of the Posterior Probability Distribution

If we followed the normal procedure of maximum likelihood analysis[6], we would choose those values of X, Y and N which jointly maximized $P(E/S)$. The result (for events in which no counter was saturated) would be very nearly the same as that obtained by maximizing χ^2, since in this case the difference between $\log P(S/E)$ and $(s - 3)\chi^2$ involves only terms of order $m_i^{-1/2}$ and smaller, and terms independent of S. However, analysis along these lines is liable to systematic bias as shown below. Moreover, as some objection to the use of the posterior probability distribution appears in the literature[7], we consider that some justification for its use is required.

Suppose that all showers could be divided into five types denoted S_1, S_2, S_3, S_4 and S_5, and that these different types of showers occurred with relative frequencies $10^4 : 10^3 : 10^2 : 10 : 1$. Suppose, further, that these showers caused events of five types E_1, E_2, E_3, E_4 and E_5 with probabilities as shown in Table 1.

Table 1. VALUES OF $P(E/S)$, THE PROBABILITY THAT AN EVENT OF TYPE E IS PRODUCED BY A SHOWER OF TYPE S

	S_1	S_2	S_3	S_4	S_5
E_1	0·8	0·1	0	0	0
E_2	0·2	0·8	0·1	0	0
E_3	0	0·1	0·8	0·1	0
E_4	0	0	0·1	0·8	0·2
E_5	0	0	0	0·1	0·8

Then according to the standard theory of maximum likelihood, one would ascribe an event E_1 to a shower of type S_1, an E_2 to an S_2, and so on, and would say that in this description each shower had an 80 per cent chance of being correctly typed. If now we convert the above probability distribution into the corresponding frequency distribution, we obtain the following (Table 2):

Table 2. FREQUENCY DISTRIBUTION DERIVED FROM TABLE 1

	S_1	S_2	S_3	S_4	S_5
E_1	80,000	1,000	0	0	0
E_2	20,000	8,000	100	0	0
E_3	0	1,000	800	10	0
E_4	0	0	100	80	2
E_5	0	0	0	10	8

It will be seen that, while the most probable cause of an event of type E_1 is still a shower of type S_1, the most probable cause of an event E_2 is again a shower of type S_1, not S_2. Again, the normal maximum likelihood method would ascribe an event E_3 to a shower S_3 and claim 80 per cent probability of being correct. It will be observed, however, that of all the events of type E_3 recorded, only 44 per cent are produced by S_3 showers; the majority of them are, in fact, produced by S_2 showers.

The chances of correct assignment for E_1 events, which we may reasonably identify with events failing to trigger the apparatus, is 98·8 per cent, but the chances of correct assignment for all other types of events averages only 30 per cent. Thus, if, as is certainly the case, a very numerous class of small showers has a low triggering probability, the frequency of success of the standard method in analysing observed events drops from 80 to 30 per cent.

It will be seen, therefore, that if some classes of showers are vastly more numerous than others, as is the case, and if the probability distribution $P(E/S)$, the probability that an S-type shower will produce an E-type event, is not sharply peaked, then some account must be taken of the *a priori* probability of occurrence of the S-type shower, $P(S)$, in order to avoid a consistent over-estimate of the shower size. This has been done in the analysis of the air shower data by using Bayes's Theorem[6]:

$$P(S/E) = P(E/S)\,P(S)/P(E)$$

The quantity $P(S/E)$ can be meaningfully interpreted only as a relative frequency of the type discussed above. Such an interpretation is not strictly admissible in our case, since we would very rarely indeed see even two events of the same type. However, investigation of the form of the function $P(S/E)$ as a function of S for various different events E has shown that large numbers of events are sufficiently similar to justify the use of this quantity.

It should also be pointed out that we cannot claim freedom from bias in the determination of any quantity which we may wish to estimate about a shower using the analysis programme described. If, for each shower, we had been concerned to find the most probable value of N, the shower size, without at the same time requiring to know the core location, then we should maximize $P(N/E)$ defined as:

$$P(N/E) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} P(S/E)\,dX\,dY$$

This has, in fact, been done by us for a sample of showers as has been mentioned, and the best value of N so determined is, in general, greater by about 5 per cent than is the value computed in the normal analysis. One should, in fact, maximize the probability distribution of whatever single physical result is desired such as shower size, core location, density of particles at a particular detector, and so on. Such a course is, however, impracticable because of the volume of computation involved. The calculations mentioned above for finding the most probable value of N independent of the core location (X, Y), and for finding the probability distribution in the core location consumed some 10–50 min. of machine time per event analysed.

LIFE AT LOW TEMPERATURES

IN recent decades man has been striving for mastery of chemical, physical and climatic forces, however abstruse or remote from his usual environment. Such mastery, when achieved, would be ineffectual or even dangerous if the biological effects of the same forces had been ignored, either in their impacts on individual plants and animals or in their widest ecological significance. During the past year, temperatures lower than any hitherto recorded in the range below 1° K. have been produced by adiabatic demagnetization and their effects on the properties of matter have been studied. During the same period, Antarctica has been crossed above and the North Pole below its ice cap. It was therefore appropriate that the British Association should hold a joint session of Sections D and I (Zoology and Physiology) on August 28 to discuss life at low temperatures.

Dr. K. Mellanby emphasized that insects of a large group are killed at temperatures above freezing point and become comatose from cold before there is danger of death. Self-protective responses and development are inhibited when their surroundings are comparatively warm. Many insects would be incapable both of completing their life-cycles and of avoiding extermination unless the environmental temperatures were well above zero for a considerable period each year. Such insects become rapidly acclimatized by brief exposure to a slightly colder environment. Thus, the chill-coma temperature of cockroaches kept at 30° C. is 7·5° C., but when individuals from the same stock are kept at 15° C. for as little as 24 hr. they afterwards move actively at 2° C. Similarly, the alarm reaction of larvæ of the yellow fever mosquito (*Aedes aegypti*) can be elicited at lower temperatures after exposing them for 24 hr. to colder water. The processes of acclimatization in insects are rapidly reversible, and their underlying mechanism remains a mystery. Insects of a second large group survive exposure to temperatures below freezing point provided that they remain supercooled. Crystallization of ice in their tissues is fatal to them. The degree to which they can be supercooled depends on the duration of exposure to that temperature. It also depends on the water content of the tissues and of the material in the gut. No material exists more water-proof than insect cuticle. Nevertheless, when a drop of moisture freezes on the outer surface of a supercooled insect the tissue fluids beneath the cuticle are instantly inoculated with ice and freeze. Recently, Asahina and Aoki[1] reported that certain moth larvæ survived freezing in liquid air under conditions in which the greater part of their body-water was converted into crystals of ice situated outside the individual cells composing the tissues. Dr. Mellanby pointed out that, from an ecological point of view, liquid air is not an important habitat. On the other hand, witnesses of the advent of spring in the Arctic describe the abundance of active insects before the snow has melted sufficiently to uncover sheltered spots with warmer micro-climates[2]. The third group of insects which survive freezing at low temperatures may, therefore, be larger and more important than hitherto supposed.

Rome and Cape Cod are at approximately the same latitude (42°). It was therefore surprising to learn from Dr. J. W. Kanwisher that temperatures between − 15° and − 30° C. are frequently recorded on the shore at Woods Hole in winter. The intertidal molluscs are in open air for 6 hr. or more around low tide twice each day. When not covered by sea water the internal temperatures of oysters, mussels and periwinkles are almost identical with the atmospheric temperature. At − 15° C., 60–85 per cent of the water in the bodies of these molluscs was frozen. Nevertheless, intact molluscs of the same species recovered fully when thawed after freezing to the same extent. Histological sections of tissues from the frozen animals showed remarkable distortion of the muscles and of the internal organs by ice crystals situated outside the cells which were shrunken. Within a few seconds of thawing the microscopic anatomy was normal. When water crystallized as ice the tissues were exposed to increased salinity, reaching a maximum at − 20° C. The tissues of the intertidal molluscs became isosmotic with concentrated solutions of salt to which they were exposed experimentally. A change in temperature of 10 deg. C. altered their oxygen consumption by a factor of 2 in the range above 0° C. and by 50 below 0° C. An increase in the salt concentration above zero equivalent to the increased salinity of partially frozen sea water cooled by 10 deg. C. reduced the oxygen consumption of the molluscs by a factor between 10 and 20. The striking alteration in the $Q_{10}(O_2)$ of the frozen animals cannot, therefore, be entirely explained by the combined effects of raised salinity and reduced temperature. Decreased diffusion of gases and increased viscosity of residual tissue fluids may also be involved. Many molluscs are immobile at 0° C. Some teleost fish, on the other hand, swim in Arctic waters at a temperature which remains steadily at −1·7° C. at the bottom and fluctuates near the surface between −1·7° C. below the ice in winter and +7° C. after the ice has melted in summer. The freezing point of blood from teleosts in temperate waters is between −0·5° C. and − 0·8° C. The freezing point of plasma from five species of deep-water Arctic fish was between − 0·9° and − 1·0° C. These fish were actively swimming with their tissue fluids in the supercooled state. They were in no danger of being seeded with ice crystals in their own ecological niche, but when brought near the surface on which ice was floating they soon froze throughout and perished. By contrast, the plasma of the Arctic surface fish froze at − 0·8° C. in summer and at − 1·5° C. in winter. The osmotic concentration of their body fluids had doubled before winter set in, so that they became supercooled by less than 0·4 deg. C. The risk of freezing was thus reduced when ice formed nearby. Dr. Kanwisher's demonstration that animals can retain full activity in the supercooled state has introduced a new conception into low-temperature ecology.

The practice of storing semen in the frozen state at low temperatures is no longer new. Nine years have passed since the report was published that glycerol protected avian spermatozoa against damage during freezing and thawing[3]. Seven years ago the possibility of banking glycerol-treated frozen bull semen was discussed at the British Association. Since then the technique has been adopted at every major cattle-breeding centre where artificial insemination is practised. A review by Dr. C. Polge, the leading authority on the subject, was therefore welcome. He said that it was essential to restore the motility of a high proportion of spermatozoa in semen to be inseminated after freezing to and storage at low temperatures. Dilution to contain a suitable concentration of glycerol and a slow rate of cooling are the two procedures vital for preserving sperm from most mammals. Human spermatozoa are exceptional. Some survive when ampoules containing untreated semen are frozen rapidly by immersion in liquid nitrogen at − 196° C. Spermatozoa of the bull and other mammals are killed by rapid cooling either above or below zero. Physico-chemical changes in the cell membrane may be responsible. Ultra-rapid cooling might cause instantaneous formation of minute intra- and extra-cellular ice crystals. Slow cooling results in growth outside the cells of larger crystals which might be less destructive; simultaneously, however, the concentration of salts rises and the spermatozoa are pickled in strong brine. Glycerol buffers the salts during freezing and permits slow cooling to avoid thermal shock. Other neutral solutes act similarly, but glycerol is unique in its lack of toxicity in high concentrations at low temperatures. The optimum initial concentration of glycerol is approximately 10 per cent for protecting bull spermatozoa, but varies for sperm of other species according to their electrolyte sensitivity and is 0–5 per cent in human and 30 per cent in rabbit semen. The motility of glycerol-treated spermatozoa of ram, boar and rabbit is high after freezing, but the fertility of the thawed semen, assessed by artificial insemination, has so far been reduced or abolished in these species. Human pregnancies have been reported in the United States following insemination of glycerol-treated frozen semen[4], but no critical experiment has been or is likely to be carried out in Great Britain. The fertilizing capacity of bull semen is not impaired by addition of glycerol and prolonged storage at – 79° or –196° C., as judged by the proportion of cows which become pregnant and the millions of normal calves already born as the result of its use. Semen of the 1952 Cambridge vintage, including samples from a bull now dead three years, still show little, if any, reduction of activity or fertilizing capacity. Farmers are already exploiting a wide choice of bulls not previously at their service. When results of progeny tests on young bulls are obtained, large stocks of semen from the best sires will be available locally and for export. Great improvements in cattle are anticipated throughout the world. Eventually, perhaps, the technique will be applicable to other farm animals.

A wide variety of other mammalian cells and tissues can now be frozen and stored without loss of viability in media containing glycerol at low temperatures. The story of how bone marrow came to be preserved in this way was told by Dr. D. W. H. Barnes. The starting-point was Jacobson's discovery in 1950[5] that mice could be saved from death after lethal doses of X-rays if, afterwards, fragments of infantile mouse spleen were inserted intraperitoneally. The explanations proposed were either that a chemical agent from spleen protected tissues sensitive to irradiation or that hæmopoietic cells from the implanted tissue repopulated the bone marrow, which would have been totally destroyed by the doses given. The report by Lorenz[6] that marrow from guinea pigs would protect mice of certain strains boosted the humoral theory. However, Barnes and Loutit had evidence that any treatment which killed the splenic cells also abolished their protective effect. One such treatment unlikely to harm a chemical agent was storage at + 4° or at – 15° C. Splenic tissue was therefore treated with glycerol and cooled to – 79° C. by the method used for preserving the viability of ovarian tissue. When the material was thawed and injected into mice after irradiating them with the lethal dose of 950 r., the proportion of survivors was as high as in the control group treated with fresh spleen. There was no loss in potency of tissue after 83 days at – 79° C. Rat bone marrow was then found to be effective in treating irradiated mice, and Barnes observed an early regeneration of hæmopoietic tissue. There are distinctive differences between the chromosomes of the mouse and the rat, which enabled Ford and Hamerton to demonstrate large numbers of dividing rat cells in the marrow, spleen and lymph glands of the treated mice[7]. Radiation had destroyed the ability of the animals to react against the foreign cells which had therefore colonized the damaged hæmo- and lympho-poietic tissues. These mice also accepted grafts of rat skin, which survived indefinitely and were recognized by the colour and length of the hairs. Rat bone marrow which had been stored in the frozen state gave results as good as those obtained with fresh marrow.

Hitherto, the concept of animals composed of tissues from two or more species has belonged to mythology. The modern chimæra, produced after irradiation, is a brilliant departure from conventional biology. It is gratifying that the use of low temperatures should have contributed to its recognition. Hopes can now be renewed of establishing banks of frozen but viable bone marrow and other tissues to replace deficient or disordered tissues in man.

Re-animation of dead and frozen animals and man is another concept with origins in antiquity. Claims to have witnessed or effected such resurrections have been made and refuted many times in ancient, medieval and modern times. Superficial tissues can be frozen without altering the internal temperature or endangering the life of the animal as a whole, although frostbite may cause local death and loss of extremities. Man and other mammals become anæsthetized when cooled by as little as 10–15 deg. C. Claude Bernard showed that guinea pigs recovered when rewarmed from internal temperatures of 18°, but at 16° C. breathing and heart beats stopped and they died. Cooling to approximately this degree was lethal to all non-hibernators. The demonstration by Andjus[8] that rats could be resuscitated from body temperatures between 0° and 2° C. and after 1 hr. of respiratory and circulatory arrest necessitated revision of criteria of death and opened new possibilities for therapeutics and experimentation. Dr. A. U. Smith has cooled golden hamsters until breathing and heart beats were at a standstill and then immersed them in baths at – 5° C. to reduce the deep body temperature below zero. About 75 per cent of the animals froze progressively while the deep body temperature remained at the freezing point of plasma (– 0·6° C.). At the end of an hour the proportion of water converted to ice was 90 per cent in the subcutaneous tissues, 60 per cent in the brain and 50 per cent in the entire body. Nevertheless, hamsters frozen for periods up to 1 hr. recovered fully after rewarming the whole body with diathermy and giving artificial respiration. Frost-bite only occurred if the extremities had been bent in the frozen state. About 25 per cent of the hamsters became supercooled and were resuscitated completely from body temperatures as low as –5·0 C. Those which crystallized spontaneously after supercooling to temperatures below – 3·0° C. did not revive. Difficulties arose when rabbits and small primates (*Galago crassicaudatus*) were frozen at and rewarmed from body temperatures below 0° C. Heart beats, breathing and spontaneous movements were usually regained after thawing, but the animals died a few hours later, showing that present techniques are inadequate. Experiments on freezing isolated uteri and hearts suggest that eventually it may be possible to perfuse the whole mammal with glycerol and revive it after freezing at temperatures as low as those used for storing isolated cells and tissues. Much remains to be done before these results could be applied to man.

It was remarkable that this symposium should have assembled so much information not discussed at recent conferences on low-temperature biology[9,10]. Many new problems were also posed, some of which, it is hoped, will be solved by scientists of other disciplines and of the rising generation who had gathered at the British Association's meeting in Glasgow.

APPLICATIONS OF CRYSTALLOGRAPHY TO CHEMISTRY

SECTION B (Chemistry) of the British Association on August 29 devoted a morning session of the annual meeting held in Glasgow to a discussion of the chemical applications of modern crystallography. The meeting was well attended and three papers were presented dealing, respectively, with applications to organic chemistry, inorganic chemistry, and with the packing of molecules in crystals.

In his paper on "The Measurement of Molecules by X-Rays" Prof. J. Monteath Robertson first outlined the classical methods and concepts of organic chemistry by means of which the relative positions in space of all the atoms in many hundreds of thousands of organic molecules have been determined, starting with the fundamental ideas of Kekulé and Archibald Scott Couper of Kirkintilloch. In contrast, the X-ray crystallographic method, developed during the past forty-six years, proceeds by direct measurement and calculation from the diffraction pattern. Kekulé's formula for benzene was shown and compared with the latest electron density section evaluated in the plane of the molecule by Prof. E. G. Cox[1]. This shows a time average of the distribution of electrons, and the atoms stand out as peaks on the contoured diagram. The main cause of the blurring of the atoms in this diagram is the fairly large amplitude of thermal movement that they possess in the crystal even at −3° C., the temperature at which the measurements were made. The motion is mainly an oscillation of the whole molecule of amplitude 7–9 deg. about the six-fold axis.

Similar sections of the naphthalene and anthracene molecules were shown, based on a very complete evaluation of the X-ray intensity data[2]. These crystals have higher melting points than benzene, and the thermal movements of the atoms, although still large, are less than in benzene. The definition of the atoms is now so good that the bond-lengths can be estimated to within a few thousandths of an angstrom.

Further elaborate refinements have recently been carried out on these molecules to try to obtain evidence regarding the distribution of the electrons that form the chemical bonds between the atoms. Briefly, the method consists of calculating the theoretical distribution of electrons in an isolated or non-bonded carbon atom. The thermal movement, which smears out the electron distribution, is then carefully calculated from the X-ray intensities. The theoretical atoms, each with its proper thermal movement but non-bonded, are then subtracted from the experimentally observed electron distributions. Any residual electron density may then be attributed to the effect of the chemical bonds. At this limit of refinement the accuracy of the observations (the measured intensities) is not sufficient to yield really conclusive results. But the results which have recently been obtained by D. W. J. Cruickshank[3] provide fairly definite experimental evidence for a ridge of residual density running around the aromatic rings and along the directions of the chemical bonds. This is in striking agreement with chemical theory for aromatic systems.

In addition to this work on simple molecules, a second and most important application of the X-ray diffraction method is in dealing with new, chemically unknown or incompletely known structures, where the object of the work is not so much extreme accuracy as just to locate the atoms in order to discover the structural formula. Serious problems of phase determination now arise, and the most generally successful method has been the use of a single atom or small group of atoms somewhat heavier, or containing more electrons, than the atoms of the unknown carbon–hydrogen skeleton of the molecule. The method was illustrated in a simple form in the structure determination of nickel phthalocyanine[4].

With the compounds of organic chemistry it is generally fairly easy to insert a marker atom without unduly disturbing the structure. Halogen atoms may often be attached, or if the compound is an acid then heavy metal salts may be prepared. It is probably true to say that this general method has been utilized, in some form or another, in the great majority of X-ray structure determinations of complex organic compounds during the past twenty years. The list of successful determinations is now so large that it would be tedious to try to enumerate them all. The structures of many natural products in the terpene and alkaloid fields, and several important antibiotics, have been determined in this way.

To begin with, the results have generally confirmed and put on an exact metrical scale what the chemist already knew, in outline at least. But as the technique of the subject advances the solution of chemically unknown structures is becoming more feasible. Already some notable contributions have been made. In the terpene field the structures of longifolene[5], lanostenol[6], and oleanolic acid[7] have been solved. The structure of the alkaloid isocryptopleurine was solved by Fridrichsons and Mathieson[8] without any chemical data except the empirical formula, and the tropolone derivative nootkatin[9] was recently solved in Glasgow.

Much the most striking recent result in this field, however, is the solution of the structure of vitamin B_{12} by Dorothy Crowfoot Hodgkin, John White and their many collaborators[10]. When this work began in 1948 there was no information about the chemical nature of the vitamin. But during the next eight years the chemical structure of various groups within the molecule was determined. A nucleotide-like group consisting of a benziminazole ribose phosphate, a propanolamine residue and various amide groups were discovered. There was also a cyanide group and, most important, a large fragment containing cobalt which it was suspected might be a porphyrin-like nucleus. There was, however, no very direct chemical evidence as to how all these groups might be linked together.

The presence of the cobalt-containing fragment and the possibility of a nearly planar porphyrin group (the crystals are strongly pleochroic) stimulated the X-ray work. If a structure is not too complex, the presence of a single atom like cobalt, favourably situated, may sometimes lead to a very complete structure determination. But vitamin B_{12} is vastly more complex than the compounds we have been considering, and with phases based on the cobalt contribution the density maps were very blurred and confused.

At this stage help was obtained from a study of the various other compounds that had been prepared by the chemists. In addition to the wet and air-dried vitamin, two other compounds proved to be most useful. These were the seleno-cyanate derivative, $B_{12}SeCN$, with a second heavy atom, and most important of all, a hexacarboxylic acid obtained by degradation (alkaline hydrolysis) which contained the porphyrin nucleus and its side chains. This crystalline fragment, obtained by Todd and his co-workers, was much less complex than the full vitamin ($C_{46}H_{58}O_{13}N_6CoCl$ instead of $C_{63}H_{88}O_{14}N_{14}PCo$, but these formulæ were not established until later). Even this fragment, however, still represented an excessively complex structure determination.

The general method of attack was now to pursue all these structure determinations simultaneously. When some atoms or groups of atoms became fairly definite, and were confirmed by their appearance in the maps obtained from the other derivatives, then those atoms were inserted in the phasing calculations in gradually increasing numbers, which resulted in diagrams of increasing clarity and definition. The process of gradually deducing the structure by successive approximations is not, however, such a straightforward and easy task as it may sound. If a false atom is inserted in the phasing calculations it will appear in the place where it is put. But if false it will generally cause a peak of less than the expected height and be more poorly defined than would be the case with a genuine atom correctly placed. The work requires much judgment and intuition, and a continual process of checking against what is plausible on chemical grounds.

Another difficulty in this work, of course, is the tremendous amount of numerical calculation required. Each stage involves the evaluation of a triple Fourier series of several thousand terms at many tens of thousands of points throughout the unit cell. It is essentially a job for the large electronic computers; and the later stages of the work owed much to Dr. Trueblood and the computer SWAC at Los Angeles.

In the latest work the positions of all the atoms in the molecule and of about 12 out of an estimated 24 molecules of water in the wet crystal have been ascertained. This very precise and beautifully determined structure should now form a basis for the better understanding of the biological activity of the vitamin, its relationship to the porphyrins and to porphobilinogen, and may also perhaps lead to its ultimate chemical synthesis.

This example was described at some length because it illustrates better than any other the enormous power of the X-ray method of analysis when applied to the solution of complex structures. When we remember the steady advances in technique which are taking place, and in particular the design of faster and more efficient electronic computers, we begin to realize what the effect of this new method on the future progress of chemistry is going to be. In determining the positions of atoms in space, which is to a large extent the basis of chemical knowledge, we have certainly moved a long way from those first fumbling steps which were taken about a century ago.

In the next paper, by Peter Pauling, on "A Rebirth of Inorganic Crystallography", a very brief review of the progress of X-ray analysis in the inorganic field was given. The early structural data, the Bohr atom and the new quantum mechanics allowed a theory of inorganic chemical bonding to be developed which extended the co-ordination theory of Werner and the covalent bond of Lewis. This went well on the way toward giving inorganic chemistry a unified theory, but it is certainly not complete. The post-war ligand field theory has had good success in explaining certain spectral phenomena and structural anomalies, but it is still not complete, as crystallographers and chemists have shown.

The impact of these theories has caused a renewed interest in inorganic chemistry and the structures of inorganic compounds. Inorganic chemistry still does not have a unified theory, though a means of thought and a direction in which to go are known, and it is certain that a complete theory will contain most important terms based on the spatial arrangement of the atoms as determined and checked by diffraction techniques.

In the last paper, on "How Molecules Fit Together", H. M. Powell said the fact that molecules fit together at all may seem remote from social significance, but an audience is itself, in a physical sense, composed of very little other than molecules fitted together, and the lecturer's every act of thought and speech involves rearrangement of his own constituent molecules. Such matters are very complex, but some help towards their understanding may come from the study of how simpler molecules pack in non-living material.

Molecules have shapes, some rigid, some flexible, determined by the distances between their linked atoms and the angles between the links. For packing purposes each atom in the atomic skeleton may be looked upon as surrounded by a negatively charged electron cloud, so that a molecule may be pictured as something like a balloon of possibly very irregular shape. Chemical reactions, growth, drug action, carcinogenic activity, and many other matters are bound up in various ways with molecular shape. In contrast to the liquid and gaseous stages, in which molecules behave in many ways as spheres, the crystalline pattern has the molecules in fixed positions which are determined by the manner in which their shapes can be packed. A general principle is that the molecules under the influence of their attractions tend to be closely packed, globules like piles of shot, cylinders like cigarettes or sloping like packs of books in a partly filled shelf; disks parallel like a pile of plates. More localized attractions between particular parts of neighbouring molecules, for example, strong spatially directed attractions through hydrogen in neighbouring water molecules, may act in a contrary sense, and by limiting the positions in which one may be placed relative to its neighbours, may lead to very open structures such as that of ice.

In some crystals molecules are bound, through hydrogen bonds or in other ways, to form larger aggregates. These sometimes may extend indefinitely in one or two dimensions, when the problem of packing them becomes that of arranging extended cylinders, ribbons, flat sheets, corrugated sheets, or related forms. If the aggregate extends indefinitely in three dimensions it constitutes the whole crystal and there is no further packing problem so far as that structure itself is concerned.

R 31A

Molecular structures of great geometrical complexity may be designed, and sometimes a close packing is impossible. Sometimes, molecules of two or more different kinds, if they are present in some suitable mixture, will together form a crystalline molecular compound. The manner in which molecules of different kinds thus fit together in regular or irregular arrays gives further information on the general principles of molecular packing.

Among the molecular packings in crystals, which were illustrated, were those in which similar or different shapes adjoin, and some where one shape encloses another. Others may interpenetrate like the links of a chain or become interlocked in a manner analogous to that used in a zip fastener. The dimensions and regularity of patterns formed by adjoining or enclosing molecules of two kinds can be related to the dimensions of the participating molecules.

NEWS and VIEWS

Botany at the Imperial College of Science and Technology: Prof. W. O. James, F.R.S.

THE news of the appointment of Dr. W. O. James to the chair of botany and headship of the Department at the Imperial College of Science and Technology will be received with satisfaction by British botanists. He succeeds Prof. P. H. Gregory, who has been appointed head of the Department of Plant Pathology, Rothamsted Experimental Station (*Nature*, **181**, 158; 1958; **172**, 838; 1953). Dr. James began his botanical career as a student under Prof. Walter Stiles at what was then University College, Reading, and after obtaining a first-class honours degree in the University of London, for which Reading students then sat, he worked on problems of photosynthesis with the late Dr. F. F. Blackman at Cambridge. This was followed by a period at Rothamsted, where he examined the effect of potassium on carbohydrate metabolism. In 1928, Dr. James joined the staff of the Botany Department at Oxford, then under the direction of the late Prof. (afterwards Sir Arthur) Tansley. At Oxford, Dr. James has built up a very flourishing school of research in plant physiology, attention having been chiefly directed to the mechanism of plant respiration, for the elucidation of which, and the establishment of its essential identity with that in animal tissues, the work of James and his pupils has been largely responsible. This work has been described in numerous papers which have appeared mainly in the *Proceedings of the Royal Society*, the *New Phytologist* and the *Biochemical Journal*. During the Second World War, as part of the Oxford Medicinal Plants Scheme, Dr. James devoted much time to the study of alkaloid metabolism and its relation to respiration. As well as his well-known monograph on "Plant Respiration", published in 1953, Dr. James is the author (jointly with Prof. A. R. Clapham) of "The Biology of Flowers", published in 1935, in which the authors dealt with the forms of flowers of a representative selection of species and their relations to insect visitors. His "Introduction to Plant Physiology" is also well known. Since 1932 Dr. James has been one of the editors of the *New Phytologist*.

Museum of Natural History, Washington: Dr. A. C. Smith

DR. A. C. SMITH has been appointed director of the Museum of Natural History of the United States National Museum. He has been programme director for systematic biology with the National Science Foundation. Of special interest in this appointment is that, prior to his affiliation with the National Science Foundation, Dr. Smith was, for eight years, curator of the Division of Phanerogams in the Smithsonian Institution's Department of Botany. He now returns to the Institution to direct the Bureau, which includes the Departments of Anthropology, Zoology, Botany and Geology. In addition to directing the activities of the Museum of Natural History, Dr. Smith will continue his work in phanerogams, a research area of paramount importance. To date, Dr. Smith has published some 135 technical papers concerning this phase of botanical research. He received his Ph.D. in 1933 from Columbia University in New York City. Thereafter, he was associated with the New York Botanical Garden and the Arnold Arboretum of Harvard University. In addition to study and research in England, France, Switzerland, Germany, Holland and the Scandinavian countries, he has participated in several botanical expeditions to Colombia, Peru, Brazil, Fiji, British Guiana, and the Lesser Antilles.

Supreme Headquarters Allied Powers Europe: Dr. J. W. Abrams

DR. JOHN W. ABRAMS, of Ottawa, who is a member of the Canadian Defence Research Board and scientific adviser to the Chief of the Air Staff since 1954, has been loaned to Supreme Headquarters Allied Powers Europe (SHAPE) to undertake important duties in connexion with the scientific analysis and planning of Western European air defences. Succeeding him at R.C.A.F. Headquarters is Dr. J. C. Arnell, of Ottawa, the Board's director of plans. Both Dr. Abrams and Dr. Arnell assumed their new duties on September 1. General Lauris Norstad, supreme allied commander, Europe, requested Dr. Abrams's services because of his wide experience in the field of operational research and, in particular, with the various scientific problems relative to air defence systems. He played a prominent part in investigating the scientific aspects associated with the planning of Canada's air defence effort.

Research on High-energy Nuclear Particles

THE U.S. National Science Foundation has made a grant of 450,000 dollars to the University of Chicago for high-energy nuclear particle research with balloons. The team will be led by Dr. Marcel Stein, of the University. The balloon flights will be part of a project investigating cosmic rays in the region of 10,000 BeV. Large stacks of photographic sheet emulsion will be sent by unmanned 'Skyhook' balloons to an altitude of 120,000 ft. for a 24-hr. period. Pressurized, light-tight gondolas attached to the balloon will contain the stacks, each of which measures approximately 2 ft. × 1½ ft. × 1 ft. This is about five times the size of comparable film stacks which have previously been sent up. A particle from outer space, such as a proton, entering the stack collides with a heavy atomic nucleus in the emulsion and the resulting nuclear explosion generates a jet of very energetic particles. This jet, like a burst of particles in an accelerator, strikes other nuclear targets and produces a whole series of new nuclear reactions, all recorded on the emulsion stacks. The purpose of the study, which will continue for three years, is to investigate high-energy elementary nuclear particles which can only be observed at the high altitudes reached in balloon flights. Calculations show that the flights should yield a substantial number of collisions above 10,000 BeV. and as many as 30,000 interactions at the lower but still significant 100-BeV. energy level. Quantities to be measured by the experiment include: primary energies of nucleons, number of charged and neutral secondary particles, interaction mean free paths of secondary particles, cross-sections from primary and secondary interactions as a function of their energy, energy loss per collision of nucleons, angular and energy distribution of secondary particles as a function of primary energy, energy spectra of heavy nuclei, and break-up in the cosmic radiation.

New Round-the-World Telephone Cable

THE construction of a round-the-world Commonwealth telephone cable was considered at the Commonwealth Trade and Economic Conference in Montreal. It was envisaged that its provision would be based on capital contributions from all Commonwealth countries and that the new cable could be operated on a self-supporting financial basis. The first trans-oceanic telephone cable was opened in 1956 between the United Kingdom, Canada and the United States, and the construction of a further cable between Canada and the United Kingdom is expected to be completed in 1961. This would form the first part of the new Commonwealth link. The rest of the route considered by the experts would be as follows: the west coast of Canada would be linked with New Zealand and Australia, and from there the cable would run through the Indian Ocean connecting Malaya, India, Pakistan and Ceylon, and from these countries by way of Kenya to South Africa. By providing a link between South Africa and the United Kingdom, connexion would be made with trans-Atlantic telephone cables.

The order of construction must be a matter for further consideration by Commonwealth Governments, but it may be that the existing and proposed links from the United Kingdom to Canada would first be extended by a cable from the United Kingdom to South Africa and a cable across the Pacific to New Zealand and Australia; the links spanning the Indian Ocean, to be constructed later, would complete the girdle of the world. The conference estimated that the total length of a round-the-world telephone cable of this nature would be about 27,000 nautical miles, or nearly 30,000 nautical miles if the trans-Atlantic crossing is included. The construction cost was estimated at £88 million, including the trans-Atlantic cables.

Russian Scientific and Technological Literature

THANKS to the co-operation of many organizations in Britain and abroad, the Department of Scientific and Industrial Research Lending Library Unit now has a growing collection of recent Russian scientific and technological literature. Despite its imperfections, it is already the largest in Western Europe. Lists of what Russian literature has been received are being issued, but the demand for this literature is not very great. It is clear that owing to the linguistic difficulties something more than the traditional library methods of making known what is available is required. Suggestions for new services will be considered. Whenever translations of Russian into English become available the Unit obtains copies if the cost of the translations is less than the actual cost of making new translations. Nevertheless, these measures by themselves appear to be inadequate, so it has been decided to initiate a translating programme. The basic idea behind the programme is that financial assistance should be available where necessary to help specialist organizations to select, translate and arrange for the publication of the important Soviet scientific and technical literature in their fields. This programme is being drawn up to avoid any duplication with the translating activities in the United States, and details about it will be made known later. Further information can be obtained from the Unit at 20 Chester Terrace, London, N.W.1.

New 'Area of Outstanding Natural Beauty'

THE Minister of Housing and Local Government, Mr. Henry Brooke, has confirmed an Order made by the National Parks Commission under the National Parks and Access to the Countryside Act, 1949, which has the effect of establishing about 26 square miles of countryside in Staffordshire, including Cannock Chase, as an 'area of outstanding natural beauty'. The area extends between Brocton, Tixall, Rugeley and Gentleshaw and also includes Shoal Hill Common to the south-west of Cannock Chase. Government grants can be made at the rate of 75 per cent towards the cost of treating derelict land, tree planting and preservation, and removing disfigurements. Grants are also available towards expenditure incurred in making agreements or orders for public access to open country and in appointing wardens. Designation does not of itself provide any additional right of access to private land. This is the sixth such area to be established. The others are: the Quantock Hills and Surrey Hills in the south of England, the Northumberland coast in the north, and the Gower and Lleyn Peninsulas in Wales.

Corby Young Naturalists' Club

CORBY Young Naturalists' Club is now in its fourth year (*School Nature Study*, 53, No. 211; April 1958). It was formed first as a group of school children who liked rambles with someone who could identify and talk about the things they saw. From there it grew to a fully fledged club with meetings and a definite object to the rambles—a 'survey' of the local woods. Field work formed the basis of the Club. So many children were interested, and joined in the activities in their spare time, that it has been found necessary to work, not as a body, but in groups.

with older children acting as the leaders. After an excursion all gather together and the various records are taken and discussed. Any doubtful record is checked in the field. All records are then entered in a book to be held for future reference. During the school holidays other field work, such as counts of birds, counts of plants in a square, or series of squares, transects of areas, and similar studies are carried out. Certificates are awarded for individual field work, or individual study. 'Report forms' are also issued to all members to encourage them to record things they see. On these records the annual report is based. One evening a week during term-time a school classroom is hired and an indoor meeting arranged. This consists of a film or film-strip, or talk by experts on a variety of subjects ; the subjects are chosen by a committee of children. Outings to places of interest are also arranged. These include marshes, woodland areas, a heronry, a large winter roost for rooks and a winter roost for gulls. There is a small club library, from which the children may borrow books.

Courses on Nuclear Energy in Europe

A NEW edition of the "Catalogue of Courses on Nuclear Energy in O.E.E.C. Countries", covering the academic session 1958–59, has recently been issued by the European Nuclear Energy Agency of the O.E.E.C. (pp. 115. Paris : European Nuclear Energy Agency, Organization for European Economic Co-operation, 1958. 2, rue André-Pascal, Paris 16). It lists details of the courses on nuclear physics, nuclear engineering and related topics to be held in universities, technical colleges and research centres, together with practical information such as the names of the instructors or professors in charge, the durations of the courses, conditions of admission, fees, and the special pieces of equipment available. The information provided is not regarded as complete, but the catalogue should enable science and engineering students who wish to acquire a better knowledge of nuclear subjects to find out what training facilities exist and where and how to apply for them. The intending student is warned in the foreword that further information concerning any particular course should be obtained directly from the institution concerned, but it would have been perhaps wise to repeat this warning boldly throughout the catalogue, because in the case of the United Kingdom institutions, for example, the information given is neither well nor systematically chosen. To university authorities and others the catalogue will also be useful as a means of comparing the programmes of instruction in the educational establishments of the numerous countries listed and as a means of assessing the extent to which nuclear energy work has developed.

National Institute of Industrial Psychology Courses

THE National Institute of Industrial Psychology has issued details of courses and seminars arranged under its auspices during October 1958–May 1959. These include courses on personnel selection methods, held in three parts each of one week's duration, with two fourth parts, each of three days duration (open to those who have already attended the first three), on the selection of clerical personnel or, alternatively, of engineering apprentices. A course on the use of statistics in personnel management has been arranged jointly with the Institute of Personnel Management. A three-day course on staff reporting and merit-rating procedures, a five-day course in vocational guidance for youth employment officers and careers teachers, and two three-day seminars on psychological problems in inspection work and on personnel work in research organizations have also been arranged. Further particulars can be obtained from the Courses Secretary, National Institute of Industrial Psychology, 14 Welbeck Street, London, W.1.

Computer Symposia

THE 1958 Computer Applications Symposium, organized by the Armour Research Foundation of the Illinois Institute of Technology, is to be held in Chicago on October 29 and 30. The purpose of the symposium will be to discuss computing and data processing devices from the point of view of users of such equipment. Business and management applications of computers will be stressed on the first day, engineering and scientific applications on the second day. Forms of application and further information can be obtained from M. J. Jans, Conference Secretary, Armour Research Foundation, 10 West 35th Street, Chicago 16, Illinois.

A Business Computer Symposium is to be held at Olympia, London, during December 1–3, in conjunction with the Electronic Computer Exhibition being held during November 28–December 4. An opening address is to be given by the Earl of Halsbury, managing director of the National Research Development Corporation, at whose instigation the Exhibition and Symposium have been organized jointly by the Electronic Engineering Association and the Office Appliance and Business Equipment Trades Association. The papers to be presented will cover practical experience of the use of computers for pay-rolls, production planning and management, file maintenance, public utility accounting, farm accounting, banking, insurance, stores control, research and design. Enrolment forms and further information can be obtained from the Electronic Computer Exhibition, 11/13 Dowgate Hill, London, E.C.4.

Announcements

SIR ALEXANDER FLECK has been appointed chairman of the Scientific Advisory Council of the Ministry of Power, which was set up in 1948 to advise the Minister on the scientific aspects of his statutory duties. Its first chairman was Sir Alfred Egerton, followed in 1954 by Sir George Thomson.

THE Institute of Personnel Management is holding its 1958 National Conference during October 10–12 at Harrogate, on the theme "The Individual and the Organization in Modern Society". Further information can be obtained from Miss E. M. Harris, Institute of Personnel Management, 80 Fetter Lane, London, E.C.4.

A SYMPOSIUM on "The Tools of Biological Research" is to be held in the Physiology Theatre, Guy's Hospital, London, S.E.1, on October 10 and 11, when the opening address will be delivered by Sir Cyril Hinshelwood. Further information can be obtained from Mr. H. J. B. Atkins, Department of Surgery, Guy's Hospital.

ERRATUM. In the article "Partition of Proteins in Liquid Polymer–Polymer Two-Phase Systems", by Dr. Per-Åke Albertsson, in *Nature* of September 13, p. 709, 'System *G*' should read 'System *C*' in : (1) Table 1, column 3 ; (2) the legend to Fig. 2 ; (3) p. 710, column 2, eighth line from the bottom.

MODERN EDUCATIONAL TREATMENT OF DEAFNESS

UNTIL recently there has been less investigation of hearing and of auditory perception than of vision and visual perception. Modern technological advances have made it possible for workers in a number of fields to gain much new knowledge about hearing. The International Congress on the Modern Educational Treatment of Deafness, which was held in the University of Manchester during July 15–23, was attended by more than 1,000 members from forty-one countries and was the largest of its kind ever to be held. It was distinguished also for its comprehensive and eclectic character. Papers on recent advances in the physiology of hearing, the pathology and causation of deafness in childhood, experimental phonetics, psycho-acoustics and audiology and the educational treatment of deafness attracted a 90 per cent attendance throughout the duration of the Congress. Audiences that included leading medical consultants and authorities on electro-acoustics and many outstanding educators of the deaf from almost all parts of the world followed papers and demonstrations of work in each others' fields with the closest attention.

The view was frequently expressed and evidently widely accepted that new scientific data about hearing are increasingly important and indeed basic to the treatment of deafness in childhood, and that the teamwork of experts in all relevant fields which is already in operation in certain centres constitutes a necessary practical approach.

Dr. Hallowell Davis, so long well-known for outstanding experimental studies in audiology at Harvard University and the Central Institute for the Deaf, St. Louis, reported that the electron microscope has now revealed many details of structure of the sense organ of the ear. The 'hairs' on the sensory hair cells of the cochlea now stand out clearly. There are considerable and probably important structural differences between the internal and external hair cells. An alternating-current output—the familiar cochlea microphonic—comes from the external hair cells, while a direct current comes from the internal hair cells. The internal hair cells seem to resist the action of poisonous drugs and the mechanical stresses of high-intensity sound more successfully than the external hair cells, which appear to be more sensitive, more specialized and relatively recent in origin. The external hair cells make possible the detection of extremely faint sounds. Small differences in the times of arrival of individual sound waves at our two ears are detected by the external hair cells and the fibres connected to them and are one basis for our localization of the source of sound in the external world.

Microchemical studies of the fluids of the inner ear show that the endolymph within the membranous labyrinth is a tissue fluid of unique chemical composition. It has a high concentration of sodium. It has not yet proved possible to relate the possible physiological and neurological abnormalities that may be represented by recruitment and by Ménière's disease to the new physiological findings of chemistry and electro-physiology. An unexpected finding has been the demonstration of a bundle of nerve fibres that runs from the brain stem to the sense organs. Galambos has demonstrated that appropriate stimulation of this pathway (in cats under laboratory conditions) reduces the sensitivity of the ear.

Prof. Ormerod (Institute of Laryngology and Otology, University of London), in a paper on the pathology of congenital deafness, defined deafness in the very young child as due to failure to develop of some part of the auditory mechanism, or to a degeneration or a disturbance of some part, already developed, of this system. The factor interfering with the development of the ear must be operative during the first half of the period of gestation. There may be complete failure to develop of either acoustic or static parts of the internal ear. The basal coil of the cochlea may take shape but not the middle and apical turns. In the commoner form of congenital change the bony labyrinth is perfectly formed, the membranous and sensory vestibular organ is fully developed and functioning, but in the cochlea the scala media is usually collapsed and the organ of Corti is represented by a small heap of undifferentiated cells. Not all the children who suffer from congenital deafness are totally deaf, but as shown by Whetnall, the great majority have some islands of hearing and may be described as sub-totally deaf. (A similar finding has been reported from Manchester.)

Mr. Harrison, in a paper on the etiology of deafness in childhood, and Dr. Watson, dealing with factors affecting the successful use of hearing aids by deaf children, reported some results of a collaborative project for which a joint team of senior members of the staffs of the Manchester Department of Education of the Deaf and of Otolaryngology have been responsible, for a number of years, with the support of the Medical Research Council. In certain cases of deafness in childhood, for example, of malformation of the external and middle ear, capacity to hear had been improved after operative treatment, by contrast with cases of deafness associated with a history of kernicterus, which are not amenable to treatment. Familial perceptive deafness was characterized by a flattish type of audiogram, with hearing losses of about 80 decibels and by pure-tone determinations indicative of severe high-tone loss.

Dr. Goodhill (Los Angeles), in a paper given by means of a sound-recording, described recent surgical advances involving many procedures for reconstituting the middle ear, in children as well as in adults, with the view of enabling transmission of sound energy to the cochlea.

Results of systematic research on the capacity of children to benefit from the use of hearing aids were reported in several papers. Prolonged studies of groups of children in different categories of auditory impairment were stated by Dr. Watson and by Dr. Hudgins (Clarke School for the Deaf, Massachusetts) to have shown that no deduction about capacity to hear speech can be made from the pure-tone audiogram alone. In the joint investigation at the University of Manchester it had been demonstrated that some cases of perceptive deafness and most cases of conductive deafness could discriminate speech.

As regards profoundly deaf children, a study of fifty pupils of the Clarke School who were profoundly deaf, over a five-year period had shown that their speech perception scores, when tested in the condition of listening with a hearing aid, and looking, were significantly higher than in the condition of lip-reading alone, and that the scores consistently improved in both conditions.

Prof. Bordley and Prof. Hardy (Baltimore) reported that since the Hearing and Speech Center of the Johns Hopkins Medical Institutions was established in 1947, intensive medical and neurological studies of children had led to a concept of hearing problems as no longer centred principally in the ear and naso-pharynx, nor in the family background. Approximately 70 per cent of the pre-school age children referred to the Hearing and Speech Center gave evidence of central disorders of trauma or mal-development at the level of the brain, with or without peripheral involvement.

A valuable paper on hearing aids was given by Dr. Littler (Medical Research Council, London), who described the peculiar problems that arise when attempts are made to equalize frequency response of the whole aid, with its three elements of microphone, amplifier and reproducer, by the combination of selective response in two different bands of sensitivity of microphone and reproducer.

Mr. Fant (Stockholm), discussing the acoustics of speech, described intensive studies of vowel articulation which have resulted in a three-parameter specification of the vocal tract configuration. He demonstrated speech that was artificially produced. This paper was appropriately followed, at a later session, by one in which Mr. John (Department of Education of the Deaf, Manchester) reported experiments that have shown the detrimental effects of reverberation and noise in rooms on the intelligibility with which speech can be heard through hearing aids and the great deterioration in scores that accompanies increase in distance of speaker from microphone. The acoustics of rooms, in which the amount of reverberation that is present is completely tolerable to listeners with unimpaired binaural hearing, can offer the greatest difficulty to users of hearing aids. Reference was made to spectrographic studies that demonstrate the distortions of vowel and consonant formants that take place. Mr. Thomas, who has collaborated with Mr. John, read a paper on the application of their findings in architectural acoustics to the design and construction of schools for the deaf and the acoustical treatment of new schools, as now practised on their advice in many parts of the United Kingdom.

Closed-circuit television broadcasts were given during two sessions. The first was introduced by Dr. Irene Ewing, who described how the diagnostic practices of the Manchester department had grown out of her own direct and original study of the highly selective reactions to sounds made by normal very young children. Under her direction, screening tests of hearing suitable for children from four months to five years were given by health visitors from the public health departments of the City of Manchester and Caernarvonshire (in Welsh), to whom with some thousand others in many parts of the United Kingdom, she had given special training. Parent guidance and the results of home training, including the use of hearing aids, with children aged from eight months to five years, were shown by Dr. Ian Taylor and Mrs. Beaman. In a paper on this subject, Prof. Huizing (Groningen) gave results of experiments that demonstrated how a home-trained child, wearing a hearing aid from the age of sixteen months, achieved a more rapid growth of expressive language than children who had audiological treatment and conventional oral training from their fourth birthdays onwards. Prof. Huizing stressed the importance of auditory feed-back in the linguistic development of deaf children, that is, of enabling them to hear their own voices, and so far as possible their own speech.

In a short article it is possible only to mention a few of the many excellent contributions made by teachers of the deaf serving on the staffs of schools, and educational psychologists. Among the most notable was a demonstration, introduced by Father van Uden, of some methods and results of training profoundly deaf children to respond to the sound of speech and music, when very loudly reproduced. Some pupils of the Institute for the Deaf, Sint Michielsgestel, aged 11–12 years, all of whom were profoundly or sub-totally deaf, were given a lesson in the course of which they were seen composing 'play-songs' or simple melodies to which they afterwards danced. Then a similarly constituted group of girls aged 13–18 years showed their notable capacity to dance ballet to music reproduced from a battery of specially designed loud-speakers, at an average peak sound-level of 95 decibels above 0·0002 dynes per sq. centimetre. The late Dr. Becking with Father van Uden made experiments that led them to conclude that profoundly deaf children can learn to perceive feelings of vibration in the body, in response to abnormally loud sound and that these feelings are an introduction to, and an enrichment of, sound-perception in the ears, the basic principle being a feed-back between sound-perception and bodily movements.

Equally significant, in a different way, was a demonstration by closed-circuit television in which severely, profoundly and sub-totally deaf pupils from the Nursery-Infant Branch of the Royal Schools for the Deaf, Manchester, aged 7–8 years, under Miss Goldsack, showed remarkable spontaneity and capacity to express themselves verbally, with a standard of general knowledge that would have done credit to a better than average class of unhandicapped pupils. They were taught in a classroom wired for induction, which enables them to move about freely without losing the teacher's voice. Five of them had had home training. Demonstrations were given by older boys and girls, using similar equipment, from the Royal Cross Schools, Preston, and the Braidwood Schools, Birmingham. Dr. Schmaehl (Dortmund) and Mr. Mikaelian (Moscow) reported extensive use of inductance systems in their countries.

Attention was frequently directed to problems in the social development of deaf children. Miss Numbers (Clarke School, Massachusetts) and Mr. Askew, principal of the English Grammar School for the Deaf, gave details of the wide ranges of occupations that are being followed by well-educated ex-pupils of good ability. Dr. Buchli, director, Royal Institute for the Deaf, Groningen, stated that he had found that children who could not be day-pupils developed more normally when living with foster-parents than in a residential special school. Dr. Murphy (Melbourne) and Dr. Silverman, director, Central Institute for the Deaf, St. Louis, referred to deaf men and women who seek social life among others who are similarly handicapped. Dr. O'Connor, superintendent, Lexington School for the Deaf, reported use of tests and procedures for evaluating the capacity of boys and girls handicapped by deafness to benefit from attendance at ordinary schools. Mrs. Miller (Clarke School) described some methods of social training for senior pupils. An important paper by Prof. Lewis (University of Nottingham) on language perception and reasoning was supported by one from Dr. Morosova (Moscow), in which she described capacity to use words in thinking as a leading determinant of cognitive activity. Several speakers, including the writer of this article, discussed the achievement of this capacity as a factor in the social development of deaf children, and the deviation of their mental growth from normal when it is begun later than among children who are not deaf.

A. W. G. Ewing

NATURE AND GENETICAL CONTROL OF RESISTANCE IN LIVING ORGANISMS

THE nature and genetical control of resistance in living organisms was considered at a joint session on September 1 of Sections *D* and *K* (Zoology and Botany) of the British Association at the Glasgow meeting. The topics were disease resistance in plants and animals, insecticide resistance in mosquitoes and drug resistance in bacteria.

In the opening paper Dr. P. R. Day (John Innes Horticultural Institution) outlined the types of genetical control of resistance to pathogens in higher plants. These range from the single, usually dominant, gene through complementary action of two or more genes to polygenic control. There is a similar pattern in the genetic control of virulence in fungal pathogens selected by cultivation of resistant crop varieties. At the single-gene level this has led to the suggestion of a gene-for-gene relationship whereby the outcome of host infection by a pathogen depends on the alleles present at complementary loci in both organisms. A resistance gene in the host is only effective if there is a corresponding avirulence gene in the pathogen. An example of how the gene-for-gene concept may be applied comes from work at the University of Wisconsin on the inheritance of avirulence among a group of strains of *Venturia inaequalis* (apple scab) on seven apple varieties. The genes for avirulence were identified and separated in recombinant stocks. From the results of inoculations it was possible to estimate how many genes for resistance were present in each apple variety and which genes for resistance were common to two or more varieties. The interaction of gene products of the host and pathogen enables the host to recognize that the pathogen is avirulent. This recognition triggers secondary reactions which kill or limit the pathogen growth. Mutants of *Cladosporium fulvum* (tomato leaf mould) and *Melampsora lini* (flax rust) can be obtained which presumably avoid the recognition reaction and are thus virulent on a particular host resistant to the original strains.

Miss C. E. Jackson (Ross Institute of Tropical Hygiene) described the appearance of resistance to chlorinated hydrocarbon insecticides (dieldrin, BHC and DDT) following their use to control natural populations of malaria-carrying anopheline mosquitoes. Laboratory studies showed that resistance to dieldrin in a strain of *Anopheles gambiae* from Northern Nigeria was some 800 times higher than that of wild-type insects of that species and was controlled by a partially dominant single gene. A discriminating dose of the insecticide enables hybrids to be distinguished from the homozygous resistant parent. DDT resistance in *A. sundaicus* from Java was controlled by a single recessive gene. In laboratory experiments it was possible to raise the level of tolerance of mosquitoes to insecticides by exposures to sublethal doses during twenty generations of larval selection. The level of tolerance achieved was never more than seven times that of the original stock and this fell when larval treatments were stopped. This 'vigour tolerance' may be associated with inversions found in the chromosomes of treated stocks. The importance of this problem is shown by the fact that resistance to the insecticides dieldrin, BHC and DDT and its analogues is now found in eleven countries in six species of mosquito. No example of simultaneous resistance to DDT and dieldrin or DDT and BHC has yet been proved.

Dr. Mary Barber (Postgraduate Medical School, London) described three types of drug resistance found in bacteria: drug tolerance, drug dependence and drug destruction. The first two types of resistance generally arise by mutation. Drug destruction is often due to formation of an adaptive enzyme such as penicillinase in some penicillin-resistant bacteria. The initiation of enzyme production by strains previously producing none probably results from mutation. The genetic transfer of drug resistance between cells can be accomplished in the laboratory by deoxyribonucleic acid extracts (transformation), by a virus vector (transduction) and by direct transfer of a bacterial chromosome, or parts of it, when cells are in contact (conjugation). The extent of these processes in Nature is unknown, although favourable conditions exist in the human flora or in the soil. The accumulation of drug-resistant strains of *Mycobacterium tuberculosis* and *Staphylococcus aureus* in hospitals has become a major problem. A study of penicillin-resistant *S. aureus* carried in the noses of pupil midwives in a London hospital showed a rise from 24 per cent carrying such strains during their first two weeks in the hospital to 60 per cent after three months. Of the permanent hospital staff 90 per cent carried resistant *S. aureus*.

The most successful approach to the control of both bacteria and mosquitoes is likely to be the simultaneous use of two or more drugs or insecticides. This makes it less likely that resistant mutants will develop. Plant breeders also try to release new disease-resistant crop varieties having two or more different resistance genes for the same reason.

Dr. A. Kleczkowski (Rothamsted Experimental Station) surveyed resistance to virus diseases in animals and plants. Resistance in plants is in a special category because of the absence of any immunity reaction comparable to the antibodies of the γ-globulin fraction of animal serum proteins.

Plant resistance may be due to failure of symptom expression, to interference, whereby infection with a mild strain protects against infection with a more virulent related virus, or by resistance mechanisms which result in localized death of host tissue preventing virus multiplication. Virus resistance may also be due to the host being inappropriate. Although antibodies may control the spread of virus from cell to cell, virus inside animal cells is not accessible to antibody and its amount is controlled by the rates of virus reproduction and inactivation. At higher temperatures the rate of inactivation tends to predominate and this has been used to cure virus diseases.

Virulent mutants of fungal and virus pathogens, drug-resistant bacteria and insecticide-resistant mosquitoes all arise as a result of high selection pressures. These pressures can be demonstrated even in entirely natural populations, resulting, for example, in the multiplicity of strains of *Phytophthora infestans* to be found on wild populations of *Solanum demissum* in Central Mexico.

Undoubtedly more is known about the genetical control of resistance than about its nature at the present time. As more is found out about both, so we shall be better able to use and control resistance.

P. R. DAY

SCIENCE IN SCHOOLS

THE Glasgow meeting of the British Association emphasized the need to reveal and encourage scientific aptitudes from an early age, and, with this in view, a special programme for young people was devised.

The Scottish Branch of the Science Masters' Association arranged an exhibition, open every afternoon, in which typical class apparatus and experiments were demonstrated and explained by boys and girls from Glasgow schools. Both children and teachers took great interest in discovering how other schools carried out familiar experiments and confirmed well-known principles. At the same time the presence of one or two less-common pieces of apparatus, such as the van de Graaff generator, provided a little extra interest and removed the school-room atmosphere. Unilever, Ltd., had a display of charts, booklets and film-strips which are available for schools, and some of the material advantages of modern science were shown in interesting exhibitions of samples, charts and models provided by Imperial Chemical Industries, Ltd., and the United Kingdom Atomic Energy Authority.

Each afternoon of the meeting three special children's lectures were delivered concurrently, and on August 28 the boys and girls had the difficult choice of hearing Sir Lawrence Bragg on "How we hear and speak", Dr. H. Barnes on "Under-water Television" or Mr. A. E. Gunther on "Geology and Oil". Those with tickets for August 29, September 1 and 2 were in no less difficulty, since they had to choose from the following list: "Atomic Energy" by Dr. T. E. Allibone, "Prehistoric Animals" by Dr. W. E. Swinton, "Thunderstorms, Hail and Lightning" by Dr. B. J. Mason, "Exploring Flowers" by Dr. G. Taylor, "Man-made Fibres" by Mr. A. B. Thompson, "The Electronic Brain" by Dr. A. D. Booth, "Animal Clocks and Compasses" by Dr. J. D. Carthy, and "Man in Flight" by Wing-Commander P. D. G. Whittingham.

One of the features of the meeting was an open forum held on Saturday morning. Sir Alexander Fleck introduced the chairman, Dame Kathleen Lonsdale, and her panel of experts consisted of Dr. I. J. Faulkner, Mr. B. B. Lloyd, Dr. B. J. Mason and Dr. W. E. Swinton. The questions, sent in by schools in the west of Scotland, showed pronounced topicality with considerable emphasis on space travel and satellites, but the panel also had to deal with some searching questions on the nature of colour, world population and the possibility of extinction of the human species. Some uncertainty was evident among the panel when asked to define matter, but Dr. Swinton was in no doubt that the homing instinct in the pigeon was in no way due to any extra sense organ in the bird.

On Tuesday morning, at the invitation of Section *X*, some sixth-form boys read original papers. Mr. A. M. J. Hutchings and Mr. A. J. Nicholl, of the High School of Glasgow, dealt very authoritatively with "Plant Ecology of Heather, Moor and Bog", while Mr. Alan Nicol gave a concise account of "The Production of Special Steels", as did Mr. J. C. Natzio with "The Work of *Discovery II*". Both these speakers are scholars of Hutcheson's Boys' Grammar School, Glasgow. Mr. D. W. McCredie of Charterhouse read an excellent paper on "The Breeding Habits of the Hen Harrier in South-West Perthshire".

At a conference of affiliated societies, Mr. R. A. Stevens outlined the future policy of the British Association with regard to the Junior B.A. The plan requires the setting up of area committees (several are already in being and eight or nine are expected by the end of the year), which would work in co-operation with local societies to provide lectures, meeting places and organized excursions. In addition to supplying the needs of adult audiences, these area committees will do all they can to encourage school scientific societies to expand and to serve as a centre of scientific culture in the schools from which interest in science would emanate downwards into the junior classes and across into the arts side of the school. In order to give the fullest assistance to scientific societies in schools, the British Association is setting up a committee for the purpose of devising suitable visual aids, and local societies are being encouraged to organize federations of school societies in their areas for the pooling of resources and exchange of ideas. Such a plan, it is felt, would be of great value to the adult societies since it would lead the children towards them and ultimately provide a source of recruits.

It is recognized by the British Association that the present plan of holding the Junior B.A. meeting at the same time as that of the parent body is possible only in the circumstances existing in Glasgow, where the city schools have just started the new term. To hold such meetings either in the school holidays or in mid-term would be quite impracticable, and it is proposed that in future the junior meeting shall be held at the end (or beginning) of the school year in whatever area is acting as host that year.

ERIC WALKER

UNEMPLOYMENT AMONG WOMEN OVER FORTY

UNLIKE many societies where the bulk of the economic load is carried by women, Western culture in general and British society in particular have inherited a tradition that opposes the gainful employment of women. To the employer women workers present problems different from those of men. Employers declare that if a woman is single she tends to be temporary, filling in time until she is married; and that if she is married she has domestic responsibilities which may make her unreliable as a worker. The sickness-rate is said to be higher among women, though here it is difficult to get reliable statistics. A woman is also said to age sooner than a man, though her average expectation of life is greater. The precise accuracy of these statements is not known; the fact that they are widely believed creates an employment complication of considerable significance.

Four surveys of unemployment among women over forty years of age in the Southampton area have been made by Miss A. F. Young of the University of Southampton (*Personnel Management*, 40, No. 344; June 1958). The total number of women employed in the area has risen from about 19,000 in 1951 to more than 23,000 in 1956, and total unemployment has fluctuated between 363 in 1954, and 472 in 1953, or about 2 per cent of all women in work or seeking it. Of the women unemployed, the number over forty has varied between 88 in 1951 and 204 in 1953, that is, between about a quarter and a half of the total, though in the last two surveys the proportion has been about a third. The figures show that the number of unemployed older workers remains obstinately high even when, as in 1954, unemployment was at its lowest. This leads to the assumption that a hard core of unemployment exists among those over forty.

Nearly half the number were found to be married women, with presumably a husband and a home. Of the rest the proportion of single and widowed fluctuated, but averaged a little more than 25 per cent each of the total. It was found, however, that unemployed single women over forty sometimes reached as much as 30 per cent of the whole (1954). When those over forty were analysed according to their age, it was found that more than half were fifty or older (57 per cent, in 1956); and getting a job becomes more difficult the older a woman grows.

The 'social' reason for discouraging the older woman to take gainful employment is her responsibility to dependent children; this is the reason why married women so often interrupt their employment for a number of years. The surveys disclosed that, of the 68 married and 43 widows over forty, only 19 had any dependent children and, of these, 7 were over fifty, the rest being under fifty. This was the position in 1956, and the figures for 1954 show a similar situation. It became clear that the demands of young children are not, on the whole, a complication to be contended with in the employment of women over forty.

It is often alleged that the majority of older women are not available for full-time work, either because their health is not good enough or their domestic responsibilities make it impossible or, having left industry for a number of years, they cannot face the discipline and strain of full-time work. The facts do not support this contention; nearly two-thirds of the women in two of the surveys have asked for full-time employment. Full-time work is more possible for those under fifty than later. Against this survey it was found that, of the small number of women over sixty looking for work, nearly all wanted it full-time.

Allied to the older woman's availability for work is her reason for seeking it. Three main reasons were given: that the wage would be her sole income; that she wished to supplement her own resources; or that she needed to supplement the family income. A fourth category of "other reasons" included the need for companionship, inability to break the habit of going out to work, and other non-financial causes.

From the evidence of these surveys there is some substance in the saying "too old at forty" where women are seeking gainful employment. If this notion is to be broken at all, and the reservoir of available labour exploited to the full for the increasing productivity of our society, then some positive steps seem to be necessary. Apart from extending the number of employers who adapt their works to meet the needs of women, like part-time work of various kinds, they might include propaganda about the advantage of maturity, training, and direct recruitment into domestic and catering trades where there are many vacancies and where many older women could usefully be absorbed.

SOUTHERN STARS OF HIGH VELOCITY

AS might be expected from the fact that observatories of the southern hemisphere are of comparatively recent origin and have fewer astronomers and telescopes at their disposal than those in the northern hemisphere, the data for large groups of southern stars are by no means complete. This lack of data is particularly noticeable in the determination of radial velocities, a survey of which was completed for stars brighter than magnitude 5·5. After the publication of Miss Roman's "Catalogue of High-Velocity Stars", which included stars north of Dec. −20° and brighter than visual magnitude 9·5, it was considered that a complementary list of southern high-velocity stars would be of great interest, but, owing to the lack of observational data, it will probably be many years before a survey similar to Miss Roman's will be completed. With the object of serving as a basis for future observations the present finding list, including all available information, has been published*.

As the criteria for inclusion in the list are less stringent than for Miss Roman's "Catalogue", it includes 1,315 entries—approximately twice the number in the more selective northern list. Tangential velocities were computed for all stars south of the celestial equator for which reliable trigonometrical parallaxes, that is, not less than 0·01″, were available, and tangential and radial velocities were corrected for a solar motion component of 20 km./sec. towards R.A. 18h., Dec. +30° relative to the nearby stars; a few other necessary corrections are also referred to. Included in the list are the stars the space velocities of which, relative to the local standard of rest, exceed 60 km./sec. as well as stars of which only one velocity component, which exceeds 50 km./sec., is known. In addition, stars the uncorrected proper motion of which exceeds 0·5″ annually and for which no further information is yet available are included. Globular clusters, planetary nebulæ and *RR* Lyr. variables, which obviously belong to population II, have been omitted, and reference is made to a number of other limitations.

---

* Memoirs of the Mount Stromlo Observatory. No. 14 (Fourth Number of Vol. 3): Southern Stars of High Velocity—a finding list compiled by William Buscombe and Pamela M. Morris. Pp. 36. (Canberra: Australian National University, 1958.)

Of the 1,315 stars listed proper motions were available for 97 per cent, Draper spectral types for 59 per cent, reliable trigonometrical parallaxes, that is, not less than 0·01″, for 49 per cent, radial velocities for 33 per cent, and complete information for the space velocities only 18 per cent. An unexpected feature was the presence of 37 *B* stars, which are usually considered to form part of the Population I disk system in our Galaxy. It is pointed out, however, that in many cases there are large differences between the radial velocities measured from spectroscopic plates of the same star on different dates, which may indicate that some at least of these stars are undetected binaries with large ranges in velocity relative to the Sun: in nearly every case the parallax and tangential velocity component are unknown.

It is pointed out that new data concerning stars of high velocity will be available, as southern observatories have now many observational programmes under way, and reference is made to the work in progress at a number of these observatories, including the Cape, La Plata, Cordoba, Sydney, and the Yale-Columbia Southern Station, now located on Mount Stromlo, Canberra. A few new radial velocities for bright stars have been determined from Cassegrain spectra (36 A./mm.) at $H\gamma$ taken with the Mount Stromlo 30-in. reflector. Classification on the *MK* system for these and for faint stars with Newtonian spectra (90 A./mm.) from the 74-in. reflector is in progress. Forty suspected subdwarfs are included in the current observing list.

ADULT EDUCATION IN WALES

THE report of the Universities Council for Adult Education for 1956–57* is chiefly devoted to a survey of adult education in Wales.

For the purposes of extra-mural work the Principality consists of four college areas (Aberystwyth, Bangor, Cardiff and Swansea), and there are a North Wales District and a South Wales District of the Workers' Educational Association. All provision and administration of extra-mural work is carried out by the four university colleges, the areas of which differ from one another in a variety of ways. The Aberystwyth area is entire rural. The Bangor area is also rural for the most part, but it comprises in addition the industrial districts of Flintshire and Wrexham. The Cardiff and Swansea areas are predominantly urban and industrial.

The two-and-a-half million people of Wales are shared unequally between the four areas. Half of them are in the Cardiff area, while Aberystwyth serves a population of about 300,000 scattered over an area which covers almost half of the Principality.

The development of extra-mural work has also varied from area to area. After some tentative beginnings before the First World War, Aberystwyth appointed a director of extra-mural studies in 1920 and, with a small nucleus of full-time tutors, an extra-mural department came into existence. Workers' Educational Association work in the area has not been inconsiderable, but, unaffected by industry, the country folk of this area have not responded so readily to the appeal of an association of workers as have the inhabitants of the other college areas.

The course of events in the other three colleges has been quite different. A South Wales District of the Workers' Educational Association was formed in 1907. This was reconstituted as a Welsh District in 1910 and served the Principality as a whole until the establishment of a North Wales District in 1925. University teachers took a leading part as pioneers for the Association, and throughout the inter-war period the actual organization of extra-mural work in South Wales was conducted largely through the Workers' Educational Association District. Departments of extra-mural studies can scarcely be said to have existed at Cardiff and Swansea until, at the end of the Second World War, the senior staff tutor was appointed secretary of the Swansea joint committee and a tutor in charge of extra-mural classes was appointed at Cardiff. There are still no directors at these two Colleges, though such appointments are contemplated in the present quinquennium.

At Bangor the alliance between College and the Workers' Educational Association was closer still, and the extra-mural work was administered to a considerable extent through the Association's district officer.

Each responsible body has had its own particular story of successes and difficulties. The voluntary bodies in South Wales expanded their work in a spectacular way during the industrial depression of the nineteen-thirties, when a considerable amount of money from the Carnegie Trust was made available to them. In the post-war period, on the other hand, the programmes of these voluntary organizations have dwindled to little more than half their former size, while those of the extra-mural departments of Cardiff and Swansea have grown apace. A great deal of pioneer work was done by the Aberystwyth department during the war years, and although the high figures reached then have not been fully maintained in more recent years, the present volume of work is at least twice what it was before the War. In the Bangor area there has been a striking expansion of Workers' Educational Association classes since the War and an appreciable increase in the classes conducted by the extra-mural department.

---

* Universities Council for Adult Education. Report on the Year 1956–1957. Pp. 27. (Bristol: W. E. Salt, Hon. Secretary and Treasurer, c/o Department of Adult Education, The University, 1958.)

Aberystwyth was the first to break away from the customary restriction of extra-mural work to tutorial and sessional classes, but, since the War, Cardiff has also been conducting an appreciable number of terminal and short courses, while Swansea has recently embarked upon a considerable programme of short extension courses. Apart from the addition of a few short extension courses, Bangor still limits itself to tutorial and sessional courses.

The Adult Education College established at Harlech in 1927 had thirty-nine students in residence for the session 1956–57, and fourteen others attended for a term or two. Almost all the sessional students were drawn from within the Principality, and about half of them were manual workers. But Coleg Harlech has always endeavoured to bring its Welsh students into contact with those of other nations, and this year most of its terminal students and one or two of its sessional students came from such countries as Austria, Hungary, Germany, Denmark, Jamaica and the United States.

Whereas the intensity in industrial South Wales is only slightly more than the average for England, class units in the predominantly rural areas of Aberystwyth and Bangor are three times as numerous as they are in England in relation to population. This is as true of tutorial and sessional classes as it is of other kinds of work.

The subjects of study do not differ fundamentally from those conducted by the other extra-mural departments of the United Kingdom, except that Welsh history predominates over other kinds of history, and Welsh literature over other literatures. Although conditions have changed in recent years, the persistence of old interests is revealed by such facts as that the physical and biological sciences are completely overwhelmed by the humanities, that courses on religious subjects figure about twice as prominently as they do in England, and that there are relatively few courses in the visual arts.

One of the major problems is that of finding sufficient part-time tutors who are really qualified for university work, and this is particularly acute in the rural areas. Each College has five full-time tutors, and these, together with members of the intra-mural staffs, take a third of the classes. In the Aberystwyth and Bangor areas it is often difficult to take full advantage of the teaching staffs of the colleges because most classes within a radius of forty miles from the college centre are conducted in Welsh, a language which three-quarters of the intra-mural staffs do not understand. Each college is obliged to depend upon part-time tutors—lecturers in training colleges and theological colleges, school teachers and ministers of religion—for the bulk of the teaching. The need for a substantial expansion in full-time staffs remains.

INFLUENCE OF CERTAIN INORGANIC IONS ON THE HATCHING OF THE POTATO ROOT EELWORM, *HETERODERA ROSTOCHIENSIS* WOLLENWEBER

By Dr. C. ELLENBY and A. B. GILBERT

Department of Zoology, King's College (University of Durham), Newcastle upon Tyne

PREVIOUS studies on the influence of salts on the hatching and emergence of larvæ of plant parasitic nematodes have approached the problem largely from the point of view of their possible osmotic effect[1,2]. However, the demonstration that the hatching-factor of the potato root eelworm possesses cardiotonic properties[3] suggested that the nature of the ions might be of importance. As already briefly announced[4], this we have found to be the case.

After a preliminary soaking in distilled water, cysts have been stimulated with solutions containing chlorides of sodium, potassium, calcium and magnesium, singly or in various combinations; each solution also contained a quantity of a concentrated hatching-factor preparation free from inorganic material, at a strength 1/5 of its optimum to give scope for increased or decreased hatching. A single-cyst technique was used[5] and a logarithmic transformation for statistical analyses[6]. In general, we have found that chlorides of the monovalent ions had a depressing effect, that is, hatching was lower than in the hatching factor alone; with the chlorides of the divalent ions hatching was higher. There was also some evidence of antagonism. No emergence took place in the salt solutions without hatching factor.

In most of our experiments, all salt solutions have been equivalent osmotically to 2 m*M* potassium chloride, so that it has always been possible to compare the different metallic ions independently of any osmotic effect. But in some experiments, a series of different concentrations has been employed, always so that it was possible to compare iso-osmotic solutions of the different salts. In some cases, we have controlled the possible influence of osmotic factors on the performance of the hatching factor alone by the addition of an appropriate quantity of glycerol.

Particular attention has been paid to potassium and calcium ions, in view of their known effect on heart action. The results of a series of experiments are summarized in Fig. 1. Although carried out at different times during 1957, the experiments were sufficiently similar to justify combining their results for purposes of presentation, and, in the diagram, each point is a mean value based on a number of experiments. Most of the experiments were carried out at concentrations equivalent to 2 and to 0·2 m*M* potassium chloride, the values for higher and lower concentrations being based on fewer experiments. The line representing hatching factor alone is based on nine lots of cysts in five separate experiments, four with hatching factor alone, and five with glycerol added to bring them to various concentrations

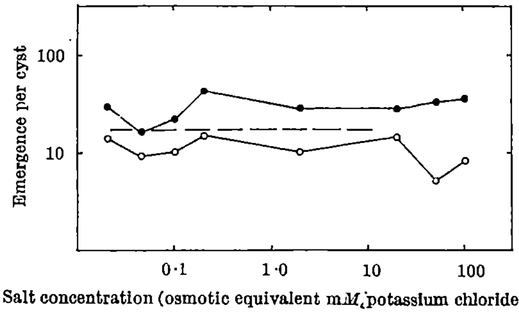

Fig. 1. Influence of potassium chloride and calcium chloride on hatching-factor activity. Values, being based on a logarithmic transformation, are essentially geometric means on a double log grid.

●—●, Hatching-factor + calcium chloride; — —, hatching-factor alone; O—O, hatching-factor + potassium chloride

covering the range of the diagram up to 20 m*M* potassium chloride: there were no significant differences among these results, and the dotted line is based on an over-all mean.

Salt concentration had little effect, emergence being fairly uniform over the 5,000-fold range of concentrations examined; but, clearly, emergence was higher in solutions of hatching factor containing calcium ions than in those containing potassium ions. Of the sixteen lots of cysts tested with potassium chloride and hatching factor in the various experiments, fifteen gave hatches lower than their appropriate control; for calcium chloride, thirteen out of sixteen gave higher values. In fact, potassium usually about halved hatching and calcium doubled it. Since, in general, larval emergence is proportional to log hatching factor concentration[7], the over-all increase in emergence between potassium-containing and calcium-containing hatching solutions is equivalent to increasing the concentration of hatching factor about twenty times.

There is chemical evidence that, like the cardiac glycosides, the hatching factor contains an unsaturated lactone group[8]; for this reason, and because of its cardiotonic activity, it was suggested that it might act by influencing ion transport[3]. The influence of ions on hatching-factor activity is consistent with this view: it derives additional support from the results of experiments with quinidine sulphate. Whether quinidine-like agents act on cardiac muscle by reducing permeability to potassium ions[9], or by acting directly on the carrier mechanism[10], it is agreed that they influence ion transport in some way. It is therefore particularly interesting that quinidine sulphate has a powerful effect on the activity of the hatching factor in the presence of potassium ions. The addition of 3×10^{-6} *M* quinidine sulphate to a hatching-factor solution had no significant effect on its activity, emergence being 44 larvæ/cyst in hatching factor alone and 39·5 with the drug added. In hatching factor + 2 m*M* potassium chloride, hatching was reduced significantly to 17·2; however, the addition of 3×10^{-6} *M* quinidine sulphate to this solution completely nullified the potassium effect, emergence being 43·7.

These experiments were all carried out with cysts from the same source and, in repeat experiments, reasonably consistent results were obtained. However, lack of the same consistency with cysts of different origin suggested that the ionic contribution of the cyst contents might be of importance; and a number of experiments have been carried out which suggest that this may indeed be the case. In the first, four lots of cysts were soaked in solutions of sodium chloride, potassium chloride, calcium chloride and magnesium chloride, respectively, all iso-osmotic with 2 m*M* potassium chloride; a further lot was soaked in distilled water. After a fortnight, they were washed, and then all stimulated with hatching-factor solution. At the end of a week, emergence from the cysts soaked in the salt solutions was about three times as high as emergence from the cysts soaked in water. A repeat experiment, using iso-osmotic glycerol instead of water for the control, gave similar results. The effect decreased with time, so that, in some cases, the final hatches did not differ significantly. However, most of our experiments were carried out with sub-optimal concentrations of hatching factor and there is evidence that, with stronger solutions, the initial response is so much higher that a larger total hatch results. The effect can also be reduced by soaking the cysts in water for two weeks, after the salt soaking; but in some experiments it persisted after this and even after more rigorous treatment. In one experiment, cysts were removed from the salt solutions after a fortnight, washed, and allowed to dry at room temperature. They were maintained air-dry at 23° C. for a fortnight, soaked for a further two weeks in distilled water, and then stimulated with hatching factor in the usual way. Emergence from the originally salt-soaked cysts was significantly higher than from the originally water- or glycerol-soaked cysts otherwise treated identically.

Experiments on the ionic pretreatment of cysts are not sufficiently advanced for us to speak with confidence of differences due to particular ions. But there is evidence that such differences may exist. In the experiment just described, although the hatches from all the salt-soaked cysts were higher than controls, the differences were highest in the case of potassium chloride and sodium chloride, and the effects were apparently more persistent. Experiments are still proceeding, and a full account will be presented in due course, but already it can be said that it is not improbable that some of the differences in the behaviour of cysts from different sources may be due to the ionic environment to which they have been subjected. Possibly this factor may be partly responsible for the differences between cysts from different sources to which Fenwick has directed attention[7].

The experiments on the influence of ions were only made possible by the gift of a sample of a hatching-factor concentrate free from inorganic material; for this we offer our grateful thanks to Dr. G. J. Janzen, of the Proefstation voor Aardappelverwerking, Groningen. The work forms part of a programme supported by a grant from the Nuffield Foundation, for which we should also like to express our gratitude.

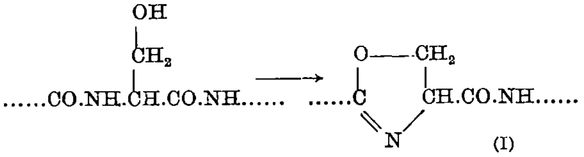
MECHANISM OF ESTERASE ACTION

Nature of the Reactive Serine Residue in Enzymes inhibited by Organo-Phosphorus Compounds

THERE is now overwhelming evidence[1] that the inhibition of cholinesterase, chymotrypsin and other esterases by di-*iso*propyl phosphorofluoridate and other organo-phosphorus compounds involves the phosphorylation of only one of the many serine residues present in the enzyme molecule. Serine itself does not react with di-*iso*propyl phosphofluoridate in aqueous solution[2], and there must be some special explanation for the exceptional reactivity of one of the serine residues in the sensitive enzymes. There are two obvious ways in which the reactivity of a serine side-chain may be enhanced: it may be influenced by some other side-chain (for example, histidine[1]) in its proximity, or it may be chemically modified.

One chemical modification of a serine side-chain to give a possibly more reactive grouping is cyclization to a Δ^2-oxazoline, (I):



The presence of Δ^2-oxazoline residues in intact proteins has been suggested before[3] and they have been postulated as intermediates in the N → O acyl migrations which occur when serine-containing peptides and proteins are treated with acid[4].

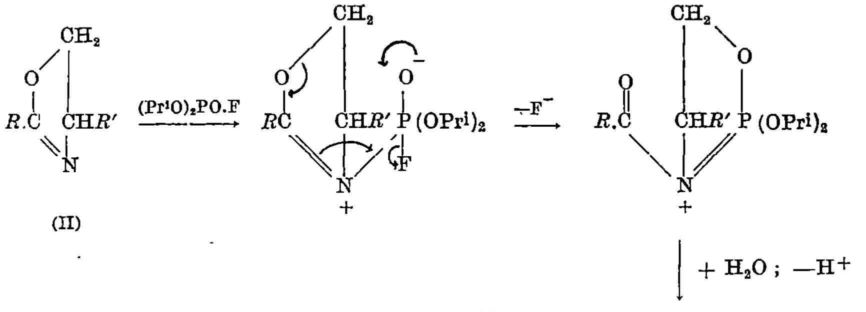


Fig. 1

We have, accordingly, studied the action of di-*iso*propyl phosphofluoridate in aqueous sodium bicarbonate at 37° on three representative Δ^2-oxazolines, namely, 2-methyl-Δ^2-oxazoline (II; R = Me; R' = H), 2-phenyl-Δ^2-oxazoline (II; R = Ph; R' = H), and 4-carbamoyl-2-phenyl-Δ^2-oxazoline (II; R = Ph; R' = —CO.NH$_2$). Although the last-named compound did not react, the two others did, the methyl compound more readily than the phenyl, giving products which yielded O-phosphoryl-ethanolamine (III; R' = H) on acid hydrolysis; control experiments showed that the reactions did not involve prior ring-opening to N-acyl-ethanolamines, followed by O-phosphorylation.

A reasonable course for the reaction is shown in Fig. 1. Our main argument, however, is not dependent on the validity of this mechanism.

As might be expected from the nucleophilic reaction of the oxazoline nitrogen postulated in the first stage, measurement of the basic strengths of the three Δ^2-oxazolines studied showed them to run parallel with the reactivity towards di-*iso*propyl phosphofluoridate, thus:

Δ^2-Oxazoline	Reactivity towards di-*iso*propyl phosphofluoridate	pK_a
2-Methyl-, (II; R = Me; R' = H)	++	5·5
2-Phenyl-, (II; R = Ph; R' = H)	+	4·4
4-Carbamoyl-2-phenyl-, (II: R = Ph; R' = CONH$_2$)	0	2·9

The decreases in basic strength observed on replacing a 2-methyl- by a 2-phenyl-group and on introducing an amide grouping at position 4 are expected consequences of the electron-attracting properties of the phenyl and amide groups.

It appears, from these results, that a Δ^2-oxazoline derivative will react with di-*iso*propyl phosphofluoridate in aqueous sodium bicarbonate, under conditions under which serine itself will not react, to give an O-phosphoryl-ethanolamine derivative, providing that it is sufficiently basic (pK_a not less than about 4). Whether or not a Δ^2-oxazoline peptide, as (I), will react under these conditions will depend on its basic strength; it seems likely that such a grouping will have a pK_a of just about 4, owing to the base-weakening effect of the adjacent peptide grouping, and may, therefore, be expected to react with di-*iso*propyl phosphofluoridate (and, presumably, also with analogous organo-phosphorus compounds) under such 'physiological' conditions.

We suggest, therefore, as a working hypothesis, that the singular serine residue present in the active centres of cholinesterase, chymotrypsin and other enzymes sensitive to di-*iso*propyl phosphofluoridate is, in fact, a Δ^2-oxazoline residue, as (I), and that it owes its unique reactivity to this chemical modification. Possible implications of this hypothesis for the mode of action of esterases are elaborated in the following communication.

Details of this work will be published elsewhere in due course; in the meantime, the experimental consequences are being actively pursued by one of us (H. N. R.) in collaboration with others.

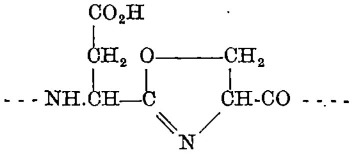
A Possible Mechanism of Action of Esterases inhibitable by Organo-Phosphorus Compounds

It has been shown that, in no less than six esterases (trypsin[1,3,5,6], chymotrypsin[1,2,5,7], red-cell cholinesterase[4], serum pseudo-cholinesterase[4], red-cell ali-esterase[4] and liver ali-esterase[4]), the uniquely reactive serine residue (-Ser*-), which is phosphorylated when the enzymes are inhibited by organo-phosphorus compounds, is situated in the sequence -Gly-Asp-Ser*-Gly-; it seems reasonable to suppose that this particular sequence must play an important part in the esteratic action of these enzymes. In this sequence, only the aspartic acid and serine side-chains are chemically reactive, and it thus seems likely that the key to the esteratic activity lies in the sequence -Asp-Ser*-. In the preceding communication, it has been suggested that the reactive 'serine' is, in reality, a Δ^2-oxazoline; if this is accepted, the structure of the key sequence is:



and it is the purpose of the present communication to show how this structure might operate as an esteratic centre.

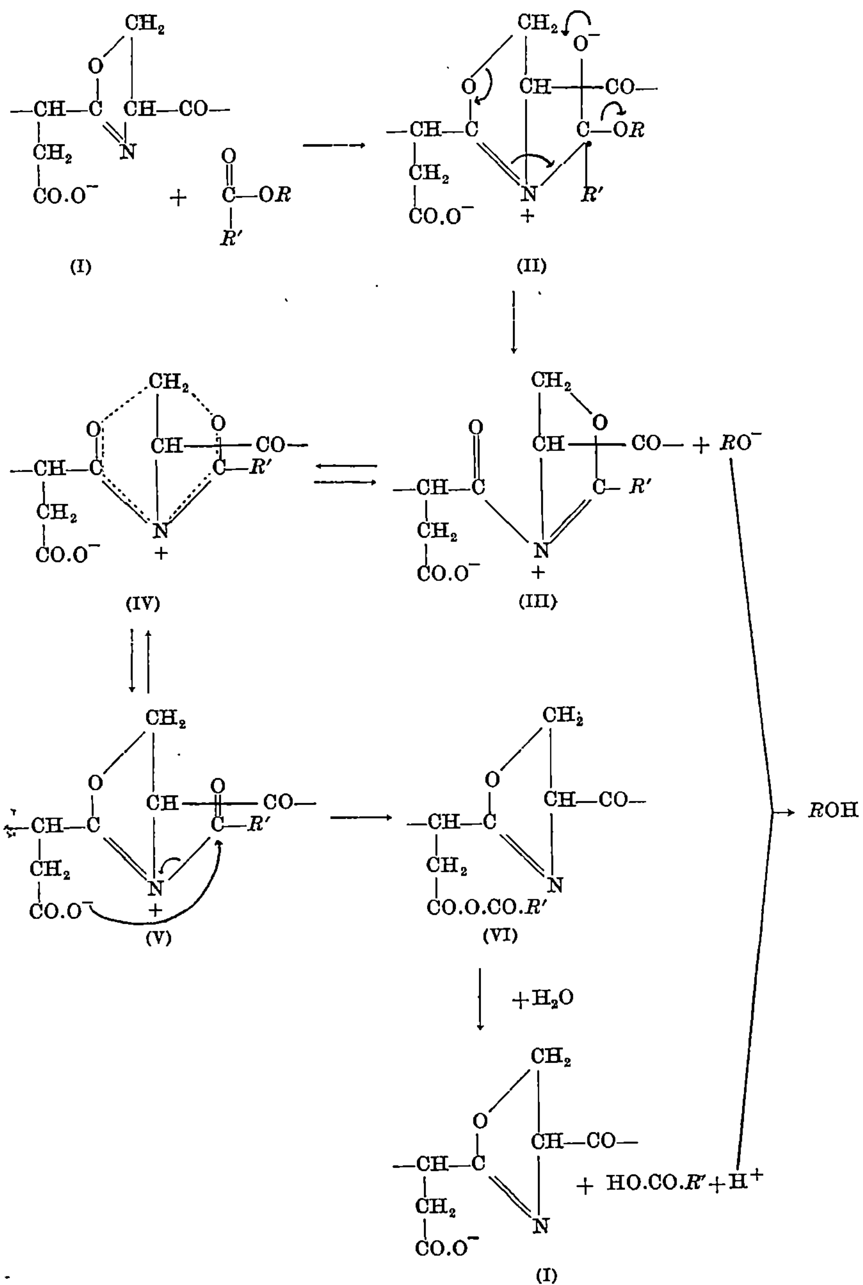


Fig. 1

The suggested esteratic process is shown in Fig. 1. The first stage involves nucleophilic attack of the oxazoline nitrogen on the ester to form the intermediate (II), which then is rearranged to the cation (III), with expulsion of the alkoxide anion; these two stages are precisely similar to those postulated in the reaction with organo-phosphorus inhibitors (preceding communication).

The cation (III) is in tautomeric equilibrium with its isomer (V), by way of the geometrically feasible transition state (IV). The essential difference between the carboxylic-ester substrates and the organo-phosphorus inhibitors resides in the difference in the position of equilibrium in the tautomeric system (III) $\rightleftarrows$ (V) and the analogous phosphorus system. In the former case, the equilibrium lies farther to the side of (V) and the carboxylic esters are substrates, whereas in the phosphorus case the equilibrium is more in favour of the analogue of (III), in consequence of which the organo-phosphorus compounds are inhibitory, undergoing the further stages of the esteratic reaction sequence only very slowly[8]. The postulated difference in the point of equilibrium in the two cases is supported by the observation that treatment of Δ^2-oxazolines with di-*iso*propyl phosphorofluoridates gives O-phosphoryl-ethanolamine derivatives (preceding communication), whereas carboxylic acid halides yield ethanolamine derivatives with the new acyl group attached to nitrogen[9].

In the next stage, the ionized aspartic acid side-chain, drawn by electrostatic forces to the neighbourhood of the positively charged nitrogen and so favourably placed to do so, attacks the carbonyl group of the $>\overset{+}{\mathrm{N}}.\mathrm{CO}.R'$ grouping. This process (compare the acylating properties of, *inter alia*, N-acyl-pyridinium salts[10], N-acetyl-imidazole[11] and N-phospho-imidazole[12]), in which the charges are neutralized, leads to the anhydride (VI), in which the acyl residue is now attached, temporarily, to the aspartic acid side-chain. It is noteworthy that, in strongly acid solution, when the aspartic acid side-chain will not be ionized, it is possible to isolate an acetyl-chymotrypsin from the products of the action of chymotrypsin on p-nitrophenyl acetate[13]; this acetyl-chymotrypsin behaves as an acetylating agent, as the protonated form of V ($R' = \mathrm{Me}$) might well be expected to do.

Finally, the anhydride (VI) undergoes hydrolysis, possibly assisted by a suitably placed histidine side-chain in an adjacent fold of the peptide chain, regenerating the enzyme (I), the acid, HO.CO.R', and hydrogen ion, which combines with the alkoxide ion liberated in the second stage, so completing the cycle. It will be seen that the suggested mechanism requires the liberation of the alcohol, ROH, from the ester, R'.CO.OR, undergoing hydrolysis, to precede the liberation of the acid, $R'.\mathrm{CO_2H}$; this is in agreement with the experimental finding[14] that, in the hydrolysis of p-nitrophenyl acetate by chymotrypsin, a relatively rapid liberation of p-nitrophenol is followed by a much slower liberation of acetic acid.

The mechanism of esterase action advanced above is in agreement with many previous experimental findings and has the advantage of affording an interpretation of the existence of a common amino-acid sequence around the reactive 'serine' in many esterases, which has already been commented on, but not interpreted, by others[4,15]. Whether or not it eventually proves to be valid, it does at least suggest further experimental studies, some of the more obvious of which will be undertaken in these laboratories.

SUBMICROSCOPIC STRUCTURE OF ELASTIC FIBRES AS OBSERVED IN THE POLARIZATION MICROSCOPE

By DR. G. ROMHÁNYI

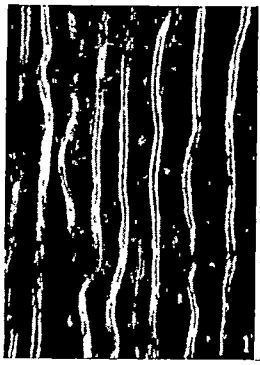
Department of Pathology, University of Medicine, Dischka Gy.-u. 5, Pécs, Hungary

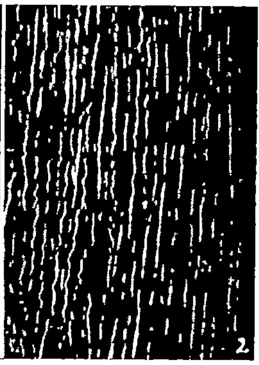
ELASTIC fibres are usually considered to be isotropic, and positively birefringent only on stretching[1]. However, in thin sections of unstretched material of human aorta and ox ligamentum nuchæ mounted in Canada balsam, I have found that they invariably show positive birefringence with retardations of about 8 mμ and 18 mμ, respectively. In a previous communication[2] I have shown that this positive birefringence of the elastic fibres in the human aorta changes into negative birefringence with retardations of about 16 mμ, when the sections are mounted in aniline after fixation in formalin, alcohol, Bouin, or Carnoy, dehydration of the deparaffinized sections in absolute alcohol, and clearing in terpineol or xylol (for further details see ref. 2).

The elastic fibres are slightly negatively birefringent already in a mixture of aniline (20 per cent) and terpineol, showing a refractive index, n, of 1·500 in an Abbé refractometer. Thus the negative birefringence of the elastic fibres in aniline cannot be regarded as being due to the relatively high refractive index of aniline ($n = 1{\cdot}58$), but rather as the optical evidence of its orientated adsorption to a structural component of the elastic fibres arranged longitudinally.

The depression by aniline to isotropy of the positive birefringence of the collagen fibres in the media of the aorta also suggests an orientated binding of aniline to the collagen fibres. Furthermore, in media with relatively high refractive indices obtained by mixing bromphenol ($n = 1{\cdot}57$) and monobromnaphthalene ($n = 1{\cdot}66$) there is no change of the positive birefringence of the elastic fibres to negativity.

The elastic fibres of the aorta of children show an axial isotropic band in aniline (Fig. 1) which, like that seen in some plant fibres[3], could be regarded as optical evidence of a submicroscopic spiral texture resulting from the compensation of the effects of the coiled filaments at their crossings at right angles in the fibre axis. Also, in aniline the elastic fibres of the ligamentum nuchæ show a broad axial compensation band as optical evidence of their spiral submicroscopic structure. These findings are in agreement with the earlier electron microscopic observation of a spiral texture of the elastic fibres





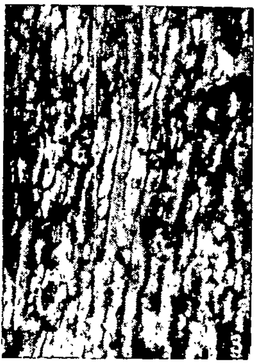


Fig. 1. Paraffin section of the aorta of a newborn infant mounted in anilin. The elastic fibres show intensive negative birefringence with an axial isotropic band

Fig. 2. Aorta of an adult. After treatment with testicular hyaluronidase for 2 hr. and staining with toluidin blue-ferricyanide at pH 4·0. The elastic fibres show intensive negative birefringence

Fig. 3. Aorta of an infant. Phenol reaction. The elastic fibres show slight negative birefringence with a poorly visible darker axial compensation band. They are surrounded by collagen fibres of stronger negative birefringence

in the ligamentum nuchæ and the skin[4]. With age the axial compensation band becomes thinner or disappears, which is probably due to an elongation of their inner spiral texture.

In recent studies with a new anisotropic staining method (buffered toluidine blue solutions at pH 7·0–2·6, followed by treatment with 5 per cent ferricyanide solution) I have found that, as a sign of their submicroscopic fibrillary structure, not only the mucoid components of the connective tissue ground substance[5] but also the elastic fibres of the human aorta show negative birefringence in green, yellow and red light, while the latter also displays isotropy in blue light, and anomalous colours ranging from dark blue to greenish-yellow, depending on the amount and sign of compensation. Thus, the elastic fibres stained with toluidine blue exhibit an optical behaviour similar to that of the collagen fibres similarly stained, which has recently been shown by Brewer[6] to be the result of an orientated adsorption of the dye molecules on the collagen fibres with their light-absorbing bonds at right angles to the fibre axis. The collagen fibres gave their staining reaction with toluidine blue above pH 4·1. However, I found that, like the acid mucopolysaccharides of the aortic media, the elastic fibres showed anisotropic staining with toluidine blue ferricyanide in regions more acidic than those of the collagen fibres. Thus the anisotropy of the toluidine blue-stained elastic fibres might be interpreted as the result of an orientated binding of the dye molecules on the structural pattern of the mucoid components in the elastic fibres.

It is known that the elastic fibres in the aorta of the newborn are faintly basophilic[7]. That is why, when stained with toluidine blue, they show only weak anisotropy. But their anisotropic staining is markedly enhanced after pretreatment with potassium permanganate (as used in the silver impregnation techniques), which renders the elastic fibres and other tissue elements more basophilic by increasing the number of negatively charged side-groups on the substrates. This also applies to the faintly basophilic elastic fibres in the skin and in ox ligamentum nuchæ. It is interesting that, after treatment with permanganate, the enzymatic susceptibility to elastase (kindly supplied by Prof. I. Banga of Budapest) of the elastic fibres of human aorta and ox ligamentum nuchæ, measured by the time of their dissolution, was more than 100 times that of the controls.

In view of the structural complexity of the elastic fibres, evidence was sought by polarization microscopy bearing on the question of the possible collagen-like nature of the filaments demonstrated in elastin by electron microscopy[8]. In this connexion it is significant that the elastic fibres invariably change their positive birefringence to negative birefringence in sections mounted in phenol. In view of the high specificity of Ebner's phenol reaction for collagen[9]—given not only by mesenchymal but also by ectodermal (cuticular, lens capsule) collagens and by the collagen fibrils reprecipitated *in vitro*—it seems reasonable to assume that the protein filaments embedded in the matrix substance of the elastic fibres are in close structural relation to collagen-type proteins.

Polarization microscopy thus provides the possibility of distinguishing in the elastic fibres two structural components: a protein demonstrable by the phenol reaction, and a mucopolysaccharide demonstrable by the toluidine blue ferricyanide method, both being present in a longitudinal or spiral arrangement. However, these two methods cannot be applied simultaneously to the same preparation. Toluidine blue-stained fibres when mounted in phenol lose their stain and show only the effect of the phenol reaction. It seems probable that close structural interrelationships between the two components and steric hindrances inhibit the simultaneous binding of the two components on the same structural basis.

The structural pattern of the elastic fibres suggested on the basis of these polarization microscopic findings is in good agreement with Hall's[10] model, which is based on electron microscopic and chemical observations of the enzymatic dissolution process of elastin. However, polarization microscopy has shown that, apart from their inner spiral architecture, a considerable portion of the mucoid component of the elastin fibres is not amorphous but longitudinally orientated along the fibres. This may possibly result from an interaction of the mucoid component with the protein filaments arranged longitudinally.

A more detailed account of these observations will be published elsewhere.

Ferromagnetism of Meteorites

THE aim of this communication is to describe some preliminary results on the magnetic behaviour of some stony meteorites, namely, Allais, Cold Bokkeveld and Orgueil. Paramagnetic resonance absorption has been used in order to be able to investigate ferromagnetic resonance and eventually paramagnetic particles or free radicals at the same time. These were not unexpected on account of the relatively high content of organic material of the selected meteorites[1]. The apparatus used was a Varian X-band microwave spectrometer. In no case was a sharp electron spin resonance observed, which seems to indicate that paramagnetic species are not present in significant concentrations. Instead a broad line occurred, which is presumed to arise from ferromagnetic resonance. The location of the maxima and the line-widths between the inflexion points are shown in Table 1.

Table 1

Name	Max. H_0 (œrsteds)	Line widths (œrsteds)
Allais	3,100	2,320
Cold Bokkeveld	3,100	2,460
Orgueil	3,100	2,250

The spectroscopic splitting factor (g), deduced assuming a random distribution for the crystallites, amounts to 2·19. This is not in disagreement with the corresponding values observed for nickel magnetite[2] and ferrites[3]. If the results of the elemental chemical analyses[4] are interpreted in terms of mineral compounds, it may be inferred that these substances are present.

It is to be noted that we have now at our disposal an objective method for studying the evolution of ferromagnetic content through the group of stony meteorites. Further research on this problem is now in progress.

We are greatly indebted to Father J. Junkes, director of the Spectroscopic Laboratory of the Vatican Observatory, for the loan of specimens of meteorites. Our thanks are also due to Varian Associates for putting a spectrometer at our disposal.

Removal of Gases in High Vacuum Systems by Metal Abrasion

CHEMICAL reaction with metal films (gettering) is a well-known process for the removal of free gas in vacuum devices. However, removal can cease once a thin layer of reaction product has formed. Thus the layer of oxide which forms on fresh aluminium surfaces at room temperature is protective[1], and so are the layers of oxide that form on the initially reactive metal, titanium[2]. Similar protective layers of compounds other than oxides also occur—see, for example, a recent review[3].

In order to overcome such limitation upon capacity for taking up gas, pumps have been designed[4] in which titanium is evaporated continuously, to provide films having fresh surfaces highly reactive with gas molecules. However, to evaporate titanium fast enough for the pump to take up gas at a useful rate (say, a few litres/μsec.), the metal must be raised above its melting point (1,670° C.), as vapour pressure data[5–7] show. Unfortunately, at such high temperatures, titanium is so reactive that there are few suitable materials from which to make hearths for holding the molten metal.

As alternative to overlaying the protective reaction products with freshly evaporated titanium, a promising idea is abrasion of the oxide, or similar layer, to expose the fresh titanium beneath. Only a very thin layer of oxide has to be removed, so scratching rather than, say, turning seems appropriate. Some preliminary experiments demonstrating the reaction of gas with a freshly abraded surface of titanium will now be described.

A trough was made from sheet titanium and in it were put a few lumps of some suitable abrasive, such as 'Carborundum' (Carborundum Co., Ltd., Manchester 17), or some pieces of an old metal file. The titanium trough was mounted in a glass bulb to which was attached both an ionization gauge for measuring the pressure of free gas and a porous ceramic appendage through which fresh free gas could be introduced at will from a surrounding jacket that could either be filled with known gases or evacuated. As a start the whole device was evacuated, baked to remove water vapour, and sealed off containing free gas at some pressure less than 10^{-6} mm. mercury. Then gas was admitted through the porous ceramic tube just fast enough to maintain the pressure at, say, 10^{-4} mm. mercury, in spite of the reaction of the gas with the hot tungsten filament and some loss to the walls (clean-up). (With oxygen the loss by reaction with the filament is appreciable—see, for example, ref. 8—but with nitrogen is negligible). When the lumps of abrasive were shaken about in the trough of titanium, or the bits of file dragged back and forth therein by means of an external magnet, the pressure fell rapidly, in less than a minute, to 10^{-6} mm. mercury. By admitting more fresh gas this fall could be demonstrated repeatedly in any particular tube. After many runs using lumps of abrasive so much powdered debris covered the bottom of the trough that gas was not taken up as readily as at the start. But in such a tube the previous best performance was maintained by dragging about the bits of file with a magnet: for in this way loading upon, and mechanical damage to, the titanium was greater.

Since air contains about 1 per cent of argon, it might have been expected that it would be impossible to reduce the pressure again below about 10^{-6} mm. mercury, and that after each successive admission of fresh gas the background pressure of free argon would increase. But this did not happen. It is true that the most rapid fall of pressure upon shaking and scratching occurred for the first hundredfold reduction; but it continued thereafter more slowly, while the ionization gauge was run. Such slow cleaning-up of the last 1 per cent remnant of air occurs probably through an exchange of argon with other gases hidden in the walls[9] and electrodes[10] or by absorption as in getters protected by argon atmospheres[11,12]. A more rapid removal of argon would be essential for improving the performance of any abrasion pump required to remove air entering continuously through leaks, as in demountable equipment; but the present form is adequate for removing gas coming from virtual leaks in sealed-off tubes like those used here.

Anomalous Dissociation of Molecular Hydrogen by Electron Impact

AN electron colliding with a hydrogen molecule can raise it to an excited state from which it may return to the ground-state by dissociating into atoms with or without emission of a light quantum. Numerous experiments with electrons up to about 30 V. energy have been carried out, but their interpretation was of heuristic value only. Neither the critical potentials for the various processes nor the dependence of the probability of a process on the electron energy was known with sufficient accuracy, and even the relative contribution of the various processes to dissociation was a matter of conjecture.

The problem was therefore attacked anew, both experimentally and theoretically. Recent observations by Corrigan and von Engel[1] show that the main contribution to dissociation comes from raising the molecule to the repulsive lowest triplet state, from which it dissociates into two hydrogen atoms in the ground-state, each with kinetic energy of a few volts; that is, no light emission occurs. This transition sets in theoretically at about 8·8 V., though earlier observations suggested an onset potential of 11–11·5 V.

Present theoretical work provides a possible explanation of certain anomalies in the region of the onset potential. In addition, there is some measure of quantitative agreement between the theoretical results of the probability of the above transition and new measurements with electron swarms.

A variational method was used to calculate the inelastic scattering cross-section associated with the transition ${}^1\Sigma_g^+ \rightarrow {}^3\Sigma_u^+$, and 120 values of the cross-section have been obtained, that is, 20 values with a final energy of the electron from 0 to 18-V. at intervals of 0·8 V. and six values with an energy loss of 8·6–15·5 V. at 1·4-V. intervals.

To obtain the dissociation cross-section as a function of the initial energy of the electron, these values should be averaged over the vibrational motion. However, if it is assumed that the result of this would be to select effectively the curve corresponding to energy loss of about 10–10·5 V., that is, one at the centre of the Franck–Condon range, then useful preliminary results can be found without detailed averaging.

All the six curves obtained have three features in common: first, in the range 0–0·8 V. above threshold, the cross-section is very small; it then rises in the range 0·8–1·7 V. above threshold by a factor of 200 or more and yet not giving values greater than the theoretical maximum which follows from the conservation of charge. Secondly, from 1·7 to 5 V. above threshold, the cross-section drops to a minimum value; and then, thirdly, in the range 5–18 V. above threshold it rises to a second maximum and falls off again.

The following table gives the values of the cross-section for an energy loss of 10 V., the critical potential for the chosen fixed interatomic distance between the nuclei ($\pi a_0^2 = 8\cdot8 \times 10^{-17}$ cm.^{2}):

Initial electron energy (V.)	10	10·8	11·7	12·5	15·8	16·7	21·7	22·5	26·7
Cross-section (πa_0^2)	0	$2\cdot4\times10^{-3}$	0·7	0·52	0·19	0·19	0·33	0·33	0·22

If the cross-section curve for 10 V. energy-loss is representative, then the theory predicts that the cross-section is very small up to 10·8 V. and rises by a large factor of order 100 to a maximum at about $11\cdot9 \pm \frac{1}{4}$ V. (since the probable energy-loss is between 10 and 10·5 V.). Because of the extremely small cross-section for the first 2 V. above the true onset at 8·8 V., we find what might be called an 'effective onset potential' between 10·8 and 11·3 V. which would be observed by experimenters using an apparatus of limited sensitivity. This result is in agreement with the earlier observations cited above. Whereas the anomalous onset has been speculatively explained[2] as entirely due to the vibrational averaging, it is now thought that the anomaly can be resolved into an electronic and a vibrational contribution both of the same order of magnitude.

Recently, Corrigan and von Engel[1] have measured dissociation coefficients in hydrogen, that is, the number of dissociations per centimetre of path in the field direction using an electron swarm in a uniform electric field of magnitude less than or equal to 100 V./cm. at 1 mm. mercury pressure. If the energy distribution of the electrons in the swarm is assumed to be Maxwellian, then the above theoretical results are in accord with the rate of dissociation observed.

I wish to acknowledge the guidance of Prof. H. S. W. Massey in my calculations.

Anthocyanins of Blood Oranges

THE fleshy endocarp of the blood orange, a variety of sweet orange, *Citrus sinensis*, contains a water-soluble red pigment which Matlack[1] showed to be anthocyanin in nature.

Factors influencing the production of anthocyanin in Sicilian varieties have been discussed by Carrante[2]; estimates of the amounts found in the juice have been made by Ajon[3]; and Patanè has published a method for its partial isolation[4]. However, no formal identification has apparently yet been made. Evidence is presented here to show that cyanidin-3-glucoside is the major pigment of the Moro variety of the blood orange, with a second pigment, probably delphinidin-3-glucoside, as a minor component.

Extraction of the pulp (2 kgm.) with methanol containing 1 per cent hydrochloric acid was followed by precipitation of the pigment as the lead complex. The precipitate was decomposed with hydrochloric acid, and the recovered pigments were taken up in butanol to which 4 volumes of benzene were then added. The solution was extracted with one volume of 1 per cent hydrochloric acid. The difficultly soluble hesperidin remained in the organic layer from which it was slowly deposited on standing. Purification was effected by cellulose column chromatography with the organic phase of butanol/$2N$ hydrochloric acid as solvent, used for separation of the black currant anthocyanins[5]. Three bands appeared on the column as elution proceeded: a rapidly moving brown band, a scarlet band, and a small slowly moving mauve band. The eluate was collected in 50 ml. fractions and a graph of the optical density at 535 mμ against fraction number indicated that the third pigment represented only about 1 per cent of the total.

The pigment in the first band was concentrated by precipitation as the lead complex and the other two by absorption on a second cellulose column as already described[5]. Paper chromatography of these concentrates and their hydrolysis products gave the following results, confirmed where possible by absorption spectra and colour tests.

(*a*) The pigment in band 1 consisted largely of red-brown material running at all times with the solvent front. Also present were traces of an anthocyanidin, chromatographically identical with cyanidin, obtained by hydrolysis of the second strawberry pigment, cyanidin-3-glucoside[6]: R_F in butanol/$2N$ hydrochloric acid, 0·75; in Forrestal solvent, 0·49.

(*b*) The pigment in band 2, amounting to about 95 per cent of the total, was a cyanidin derivative, the aglycone obtained on hydrolysis by treatment with 5 per cent perchloric acid for 30 min. at 50° C. being chromatographically identical with cyanidin. The anthocyanin behaved as a 3-glycoside, co-chromatographing with the second strawberry pigment in four solvent systems: R_F in butanol/$2N$ hydrochloric acid, 0·26; in butanol/acetic acid/water, 0·38; in *m*-cresol/acetic acid/water, 0·34; in Forrestal solvent, 0·74.

(*c*) The pigment in band 3 was a delphinidin derivative, and chromatographed as a 3-glycoside in the four solvent systems given above, with R_F values of 0·16, 0·21, 0·16 and 0·65, respectively. The aglycone obtained on acid hydrolysis was chromatographically identical with delphinidin, the hydrolysis product of delphin, obtained from blue delphiniums and purified by column chromatography: R_F in butanol/$2N$ hydrochloric acid, 0·45; in Forrestal solvent, 0·28.

(*d*) Glucose was the only sugar present in the hydrolysates from the two glycosides, co-chromatography with glucose producing no separation in three solvent systems: R_F in *n*-collidine, 0·38; in ethyl acetate/water/pyridine (2 : 2 : 1), 0·30. R_x in water-saturated *n*-amyl alcohol, 0·42 (R_x of xylose, 1·00). Galactose in these solvent systems gave values of 0·35, 0·25 and 0·33, respectively.

From the hydrolysate of the main pigment an osazone was prepared, melting point 205° C.; no depression when mixed with authentic glucosazone, melting point 207° C.; but depressing the melting point of authentic galactosazone (197° C.) by 15–20 deg.

These results identify the main pigment as cyanidin-3-glucoside, confirmed by the determination of the aglycone : glucose ratio, using the method and the molecular extinction coefficient given by Nordstrom[7].

Identification of the second glycoside as delphinidin-3-glucoside is based on its behaviour on the paper chromatogram, partition between solvents, colour tests, and chromatographic behaviour of the sugar moiety.

These observations apply specifically to the Moro variety. The main pigment of three other varieties, Tarocco, Florida and Ruby Red, is indistinguishable chromatographically from that of the Moro, and no major varietal difference seems likely in anthocyanin pigmentation.

The fruit was provided by Dr. W. P. Bitters, University of California, Riverside.

Incorporation of Radioactive Sulphur by *Thiobacillus thioparus*

IN the course of our investigations on the metabolism of sulphur in the autotrophic bacteria *Thiobacillus thioparus* we have found that this micro-organism metabolizes only the outer sulphur atom of thiosulphate. The inner sulphur atom probably does not enter the bacterial cell and is left in the medium as a sulphate ion[1]. We carried this investigation further with thiosulphate labelled in the outer position with sulphur-35 ($Na_2O_3S^{35}S$), tracing the pathway of the radioactive sulphur in the bacterial cells.

The pool of free amino-acids and related compounds were investigated in the following manner: the ethanol extract from a culture of *Th. thioparus* which had been incubated for 24 hours with radioactive thiosulphate was separated by paper electrophoresis and chromatography, after which autoradiograms were made. We proved that radioactive sulphur is incorporated into cysteine, cystine and methionine as well as in cysteic and cysteinesulphinic acids. A few other radioactive spots were also established. One of these sulphur compounds was identified as α-thiooctanoic acid, by its R_F value and from the results of microbiological tests with *Streptococcus faecalis*[2].

The whole cells of bacteria incubated in this way were hydrolysed, and the product was fractionated by paper electrophoresis and chromatography. All typical amino-acids were demonstrated in the hydrolysate; dicarboxylic acids, alanine, threonine, glycine, serine and leucine were present in particularly large amounts. We found the same sulphur amino-acids as in the ethanol extract. Besides these amino-acids some unidentified sulphur compounds were found.

Definitely different results were obtained during investigation of the alcohol extract and whole-cell hydrolysate, when the bacteria were incubated with radioactive thiosulphate for 1–10 min. only. The chromatographic analysis in this case, of course, gives the same results as for bacteria incubated with thiosulphate for 24 hours; the difference is in the autoradiograms in which no ninhydrin-positive substance has any measurable radioactivity. Instead of the known radioactive sulphur amino-acids, a radioactive spot appears corresponding to compounds which do not migrate electrophoretically at *p*H 2·7, and which do not stain with ninhydrin. The radioactivity of these substances increases with the duration of incubation. The unidentified substances which give rise to this spot are a mixture of at least two compounds which can be separated chromatographically in the system *n*-butanol—acetic acid—water (5 : 4 : 1), the R_F values of which are 0·23 and 0·52.

This and former experiments[1] lead us to suggest that the outer sulphur atom of thiosulphate reacts with some organic acceptor in the bacterial cells, forming a compound (not yet identified) detectable during the early stages of incubation with thiosulphate. This compound represents one of the steps in the metabolism of sulphur in the cell. The hypothetical organic acceptor probably reacts not only with the sulphydryl group of thiosulphate but also with the same group in other sulphur compounds. This idea arises from our experiments on *Th. thioparus* incubated in a medium containing cysteine labelled with sulphur-35. The culture of *Th. thioparus* does not develop when the sole source of oxidizable sulphur is cysteine; it only does so in the presence of thiosulphate. When *Th. thioparus* is incubated in a medium with unlabelled thiosulphate and labelled cysteine it is possible to demonstrate that after some time the alcohol extract and whole-cell hydrolysate contain the same radioactive sulphur compounds as were found after incubation with radioactive thiosulphate alone. In the medium, radioactive, elementary sulphur and radioactive sulphate ions also appear as oxidation products of cysteine sulphur. These radioactive substances cannot be solely the products of non-biological reactions between cysteine and thiosulphate, because such reactions would give rise to other compounds (following communication); nor do they originate from an isotope exchange reaction.

Reactions of Thiosulphate with Cysteine

During investigations of the metabolism of sulphur compounds in autotrophic bacteria and in higher animals, it was observed that thiosulphate reacts spontaneously with cysteine. This reaction has been studied fairly extensively, revealing some facts which may be of interest for understanding the behaviour of thiosulphate *in vitro* and *in vivo*.

The experiments reported below were performed in an apparatus consisting of a reaction vessel with a side-arm connected to an absorption vessel by a ground-glass joint. A stopcock in the joint connected the apparatus to a vacuum pump and the reactions were performed *in vacuo*.

Hydrogen sulphide was trapped by a suspension of cadmium hydroxide. Chromatograms were developed in acetic acid in phenol saturated with an aqueous solution containing 6·3 per cent sodium citrate and 3·7 per cent sodium dihydrogen phosphate. The spots were detected by ninhydrin staining. All reagents were of analytical grade.

(1) Thiosulphate (1 m.mole or more) was mixed with a solution of cysteine (1 m.mole in 5 ml.) suitably buffered with carbonate or phosphate to *p*H 7–7·4, and the mixture was left overnight at room temperature. The appearance of yellow cadmium sulphide in the absorption vessel indicated that hydrogen sulphide was evolved; at the same time a white substance was precipitated.

The hydrogen sulphide originates solely from the outer sulphur of thiosulphate, as can be shown by experiments with radioactive thiosulphate or cysteine. The hydrogen sulphide produced was radioactive only when thiosulphate labelled with sulphur-35 in the outer position ($Na_2O_3S^{35}S$) was used; it was completely inactive when the radioactivity was initially in the cysteine sulphur.

The white precipitate was identified as cysteine, but the amount represented only part of the cysteine originally present. This was interpreted as meaning that some of the cysteine was converted to a different compound. In order to study this problem the solution was investigated chromatographically. On the chromatograms there was only one well-marked ninhydrin-positive spot, with R_F value 0·04–0·05. (In the experimental conditions cysteine was deposited in too small a quantity to give a coloured spot). This spot was identical with that given by cysteine-sulphonic acid prepared by Clarke's method[1].

The formation of hydrogen sulphide, cystine and cysteine–sulphonic acid as products of the reaction between thiosulphate and cysteine can be formulated as follows:

$$R - SH + {}^{-}S - SO_3^{-} \rightarrow R - S - SO_3^{-} + HS^{-}$$

$$R - S - SO_3^{-} + R - SH \rightleftharpoons R - S - S - R + HSO_3^{-}$$

where R represents the aminopropionic radical $-CH_2.CHNH_2.COOH$.

Glutathione and dimercaptopropanol react also with thiosulphate with production of hydrogen sulphide, but the other products were not investigated.

(2) When the solution resulting from the reaction described above was warmed for several hours at 60° C., the precipitate of cystine dissolved, and the chromatograms of the solution exhibited, besides the cysteinesulphonic acid spot, another spot with R_F 0·08–0·1. This spot is supposed to be due to a new

compound, which may be called cysteinethiosulphonic acid: $R\text{—S—S—SO}_3\text{H}$. Its formation can be explained by the reaction:

$$R\text{—S—S—}R + {}^-\text{S—SO}_3^- \rightarrow R\text{—S—S—SO}_3^- + R\text{S}^-$$

This supposition is supported by the fact that a warmed solution of cysteine and thiosulphate tested chromatographically also gives two spots located in exactly the same positions as those described above. The second reason is that a compound with R_F value 0·08–0·1 is formed during the oxidation of a cysteine and thiosulphate mixture with iodine. In this case there are three possible parallel reactions:

$$2R\text{—SH} + \text{I}_2 \rightarrow R\text{—S—S—}R + 2\text{H}^+ + 2\text{I}^-$$
$$2\,{}^-\text{S—SO}_3^- + \text{I}_2 \rightarrow {}^-\text{O}_3\text{S—S—S—SO}_3^- + 2\text{I}^-$$
$${}^-\text{S—SO}_3^- + R\text{—SH} + \text{I}_2 \rightarrow R\text{—S—S—SO}_3^- + \text{H}^+ + 2\text{I}^-$$

The third reaction produces cysteinethiosulphonic acid, which can be identified chromatographically.

(3) The reaction of cysteine with tetrathionate is connected with the facts described above. When solutions of these compounds (mM : mM) were mixed together a white precipitate was quickly formed, which was identified as cystine, but other products are also formed. Curiously enough, the chromatograms of the solution revealed the existence of three spots located near one another. The two lower spots corresponded to those of cysteinesulphonic acid and cysteinethiosulphonic acid, the third presumably belongs to a compound which may be called cysteinedithiosulphonic acid, $R\text{—S—S—S—SO}_3\text{H}$. The reaction which led to the formation of this acid may be formulated:

$$R\text{—SH} + {}^-\text{O}_3\text{S—S—S—SO}_3^- \rightarrow R\text{—S—S—S—SO}_3^- + \text{HSO}_3^-$$

If the formulations of the reactions described above are correct, a way is opened for the synthesis of a new class of compounds which may be called cysteinepolythiosulphonic acids. Further studies are in progress.

Inhibition of Cholinesterase Hydrolysis of Dihydromurexine by Lysergic Acid Diethylamide and its 2-Bromo Derivative: a Selective Relationship

PREVIOUS investigators have shown that human plasma cholinesterase is strongly inhibited by both lysergic acid diethylamide (LSD) and its 2-bromo derivative (BOL). The cholinesterases of other species were less sensitive to the effects of both these substances[1-3]. Recent reports described certain newer choline esters, namely, imidazoleacrylylcholine[4,5] (murexine), imidazoleacetylcholine[6] and imidazolepropionylcholine (dihydromurexine) which are hydrolysed most readily by human plasma cholinesterase[7-10]. These observations have led us to evaluate the possible relationship between cholinesterase inhibition by lysergic acid diethylamide and BOL and cholinesterase hydrolysis of dihydromurexine. Dihydromurexine was chosen as the model substrate because it is the most active of the three esters.

Table 1. HYDROLYSIS OF BUTYRYLCHOLINE AND IMIDAZOLEPROPIONYLCHOLINE BY SERA OF SEVERAL SPECIES AND THE INHIBITORY EFFECTS OF LYSERGIC ACID DIETHYLAMIDE

1 ml. of 1 : 10 dilution of serum; 0·5 or 1 ml. of 0·1 M phosphate buffer pH 7·2; 0·5 ml. of inhibitor to give a final concentration of 8×10^{-6} M; 0·5 ml. of butyrylcholine (800 μgm./ml.) or 0·5 ml. of equivalent amount of dihydromurexine; temperature, 37° C.; incubation time, 10 min.; total volume, 2·5 ml. Choline esters were measured by Hestrin's method (ref. 11)

Substrate	Butyrylcholine		Dihydromurexine	
Species \ Inhibitor	−LSD	+LSD	−LSD	+LSD
Cat	*H*	*H*	—	—
Dog	*H*	*H*	—	—
Guinea pig	*H*	*H*	—	—
Mouse	*H*	*I*	*H*	*I*
Human	*H*	*I*	*H*	*I*

H, 90–100 per cent hydrolysis of substrate; *I*, 90–100 per cent inhibition; —, no hydrolysis of substrate.

Table 1 indicates that though all the sera tested hydrolysed butyrylcholine, only mouse and human sera hydrolysed dihydromurexine under the conditions of these experiments. Moreover, only mouse and human serum cholinesterases were inhibited by lysergic acid diethylamide. Similar findings were obtained employing BOL as the inhibitor.

Further experiments have shown that both mouse and rat brain homogenates hydrolyse butyrylcholine. However, the pseudocholinesterase of mouse brain differed from that of rat brain in two respects: (1) mouse brain cholinesterase catalysed the hydrolysis of dihydromurexine, and (2) this enzyme was strongly inhibited by lysergic acid diethylamide or BOL. Rat brain cholinesterase did not display either of these properties. Thus, in all cases tested so far, a potent inhibition of cholinesterase by lysergic acid diethylamide or BOL was observed only when the enzyme was capable of hydrolysing dihydromurexine.

These results suggest that a specific enzyme–substrate relationship (ability of some cholinesterases to hydrolyse dihydromurexine) is the basis for the selectivity displayed by lysergic acid diethylamide and BOL towards various cholinesterases. The identification and evaluation of other choline esters may aid in clarifying this observation.

Radiometric Titrations with Complexons

Among the reactions commonly used in volumetric work, only two are suitable for radiometric titrations: (*a*) reactions which result in combinations which are only very slightly soluble[1,2]; (*b*) reactions which result in complexes[3].

At first, precipitation reactions were used, one of the reactants being labelled with a radioactive isotope. The precipitate resulting from titrations was separated from the solution by filtration or centrifugation and the equivalence point was determined by measuring the activity of the solution. Thus, halides were determined with radioactive silver; manganese, uranium, thorium, beryllium and zirconium with radioactive phosphate; thallium with tetraphenylboron, etc. (*loc. cit.*).

I. M. Korenman[3] and F. G. Duncan *et al.*[4] introduced complexing reactions into radiometric titrations. Zinc, mercury and cobalt were determined by using dithizone as a complexing agent. The reaction product was separated from the solution, using the solubility of dithizone and its complexes in carbon tetrachloride (extraction). The same authors also proposed a non-isotopic tracer method, which consists in adding a radioactive isotope of another element (for example, cobalt-60) which may react with the complexing or precipitating agent only after the quantitative reaction of the cation under study has taken place.

This procedure has great advantages because it permits the choice of a convenient radioactive isotope and the determination of many cations with the same radioactive isotopes.

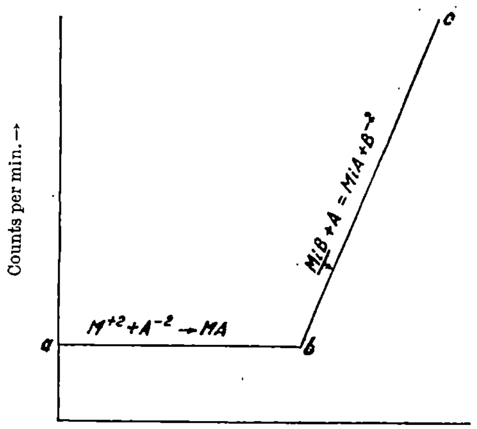
We have devised a radiometric titration depending on complexing reactions; the equivalence point is found, using a radioactive indicator in heterogeneous phase. The following procedure was employed: a cation, M^{2+}, was titrated with a complexing agent A^{2-}, and a precipitate containing a radioactive cation ($M_i{}^*B$) was used as indicator (in the heterogeneous phase). The complexing agent A^{2-} reacts with the cation M^{2+}, giving the stable and soluble complex MA. Meanwhile, the activity of the solution remains the same and is determined by the cosmic background and the ions $M_i{}^{*2+}$, arising in the dissociation of the precipitate ($M_i{}^*B$), according to its solubility product $L_{M_i{}^*B}$. After the complete disappearance of M^{2+}, the excess of added complexing agent reacts with $M_i{}^{*2+}$, dissolving the precipitate $M_i{}^*B$; the activity of the solution increases with increasing amount of complexing agent A^{2-} added after the equivalence point is reached. Fig. 1 shows the plot of the activity of the solution versus amount of complexing agent A^{2-}. The region *ab* of the curve corresponds to the reaction:

$$M^{2+} + A^{2-} \rightarrow MA \qquad (1)$$

and the region *bc* to the reaction:

$$M_i{}^*B + A^{2-} \rightarrow M_i{}^*A + B^{2-} \qquad (2)$$

In order that these reactions occur as above, the following conditions must be fulfilled: (1) the MA complex must be much more stable than the $M_i{}^*A$ complex, that is, $pK_{MA} > pK_{M_i{}^*A}$; (2) the solubility product $L_{M_i{}^*B}$ of the indicator precipitate and the stability constant $K_{M_i{}^*A}$ of the $M_i{}^*A$ complex must be related in such a manner as to shift reaction 2 to right; (3) M^{2+} must not react with the anion B^{2-} of the labelled precipitate, in order to avoid taking the radioactive cation $M_i{}^{*2+}$ out of the combination.

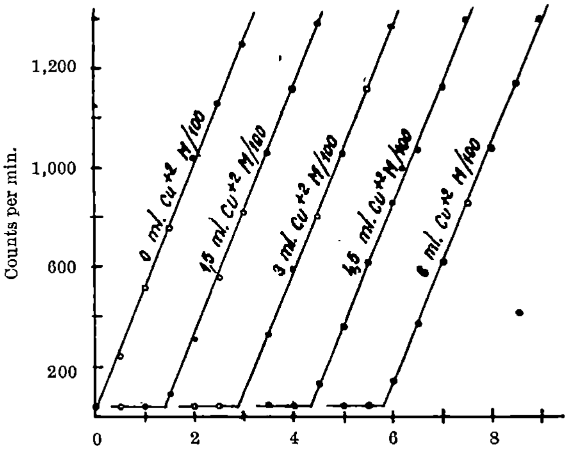


ml. complexant →
Fig. 1

The first system chosen for titrations was the following: complexon III was used as a complexing agent and radioactive silver as tracer (it gives a slightly stable complex with the complexing agent and may be used in the titration of many cations if condition 1 is fulfilled); silver has also a suitable half-life (270 days).

To get the radioactive tracer in the heterogeneous phase, radioactive silver was precipitated as Ag^*IO_3. The silver iodate is soluble, at convenient *p*H, in complexon III solutions according to condition 2. The titration of copper at a *p*H of approximately 9 will serve as an example. Fig. 2 shows the curves obtained when copper is titrated with complexon III using radioactive silver iodate as indicator in the heterogeneous phase. Curve 1 represents the titration of radioactive silver iodate with complexon without adding copper ions. Curves 2, 3 and 4 show the titration of different amounts of copper.

By this method a wide range of elements may be determined either by direct titration or by re-titration. Different complexing agents and radioactive indicators in the heterogeneous phase may be used, provided they fulfil the necessary conditions already mentioned.



ml. complexon III (*M*/100)
Fig. 2

In a paper to be submitted elsewhere the conditions in which a wide range of cations have been titrated in our laboratories will be described.

The Free Amino-Acids of the Cerebrospinal Fluid

Current literature contains confusing reports about the number and nature of the free amino-acids normally present in human cerebrospinal fluid[1]. Thus, while some investigators have detected only three to eight amino-acids[2], others have found as many as eighteen[3]. In many instances, a particular amino-acid was not present regularly, but was only observed in a few cases. For this reason, reports which suggest that certain amino-acids occur exclusively in certain diseases can only be regarded as speculative. The aim of the present work has been to establish whether or not a regular pattern of amino-acids exists in normal and abnormal cerebrospinal fluid.

Separation of the amino-acids of a number of samples of cerebrospinal fluid by high-voltage paper electrophoresis, using buffer solutions of different pH, led to the identification of between six and eight amino-acids in each sample. Two-dimensional paper chromatography gave better results, but with this method some amino-acids present only in trace amounts were sometimes insufficiently separated for clear identification. High-voltage paper electrophoresis was therefore combined with paper chromatography and the following standard procedure adopted: 5–10 ml. cerebrospinal fluid was deproteinized with acetone and then desalted electrolytically in a modified Astrup desalting apparatus provided with an outer glass vessel containing an ice/salt cooling mixture. Under these conditions, adequate desalting for the high-voltage paper electrophoresis and chromatographic separation could be obtained in 5–10 min. without destruction of the amino-acids. The desalted solution was then evaporated to dryness *in vacuo* and the residue dissolved in distilled water (1/100 volume of original cerebrospinal fluid). 5–10 μl. of this solution was applied to a Schleicher and Schüll 2043*a* paper (60 cm. × 28 cm.), and high-voltage paper electrophoresis was conducted for 75 min. at 80–100 V./cm., in a fumaric - acetic acid buffer, $p\text{H} = 1{\cdot}9$, using a Werner and Westphal chamber[4]. The paper was then dried and run as an ascending chromatogram for 16 hr. with n-butanol/acetic acid/water (4 : 1 : 5) as solvent. It was developed with the ninhydrin reagent of Levy and Chung[5]. This technique enabled a clear separation and identification of most of the amino-acids in cerebrospinal fluid to be made. Identification of cysteine–cystine, methionine, phenylalanine, and proline was achieved by running one-dimensional chromatograms (using 30 μl. of solution = 3 ml. cerebrospinal fluid) which were then developed with specific reagents for these amino-acids.

A series of twenty cases was investigated using this method, and the following twenty-five substances were regularly found in the cerebrospinal fluid: alanine, α-amino-n-butyric acid, γ-amino-n-butyric acid, arginine, aspartic acid, cysteine–cystine, glutamine, glutamic acid, glycine, histidine, leucine-*iso*leucine, lysine, methionine, ornithine, phenylalanine, proline, serine, taurine, threonine, tryptophan, tyrosine, valine and three unknown substances, two of them probably biogenic amines. Occasionally, two other substances were also found, but these disappeared after hydrolysis; their electrophoretic and chromatographic characteristics suggested that they may be peptides.

The clinical diagnoses of the cases examined included cerebral atrophy of varying etiology, postencephalitic parkinsonism, cerebrospinal syphilis, diabetes insipidus, idiopathic and symptomatic epilepsy, cerebrovascular diseases, other neurological and non-neurological diseases; some normal individuals were also included. There was no correlation between the electroencephalogram, air-encephalogram, usual routine laboratory tests of cerebrospinal fluids and blood and the spectra of the free amino-acids in the cerebrospinal fluid.

From these results it is concluded that the qualitative analysis of the free amino-acids in the cerebrospinal fluid is of no diagnostic value. The amino-acids are basic constituents of both normal and pathological cells, and it is therefore unlikely that diseases which affect only a small percentage of the total number of nerve cells will alter the spectrum of free amino-acids in the cerebrospinal fluid over and above the large quantitative variations reported in the literature.

Oxidation of Ethyl Alcohol to Acetic Acid by Proliferating Yeasts

In certain typical Spanish wines (Moriles, Montilla, Jerez, etc.), a film is formed on the surface after fermentation.

From a red wine of Galicia (Spain) I have isolated a strain of *Saccharomyces* that is able to form a film ('flor') on red wine (Fig. 1). Inoculated into grape must with a 23 per cent sugar content, this culture produces a vigorous alcoholic fermentation, typical of *Saccharomyces*, and after fermentation forms a film.

In studying the characteristics of this strain, I found that in the yeast nitrogen base for the carbon-assimilation tests of Wickerham, with 3 per cent of ethyl alcohol a pellicle is formed after 8 days at 25° C., and acid is produced; after 32 days at 25° C. the pH was 2·6 and finally 7·5 ml. $0{\cdot}1\,N$ sodium hydroxide were needed to neutralize 10 ml. of medium. The acid was exclusively acetic acid.

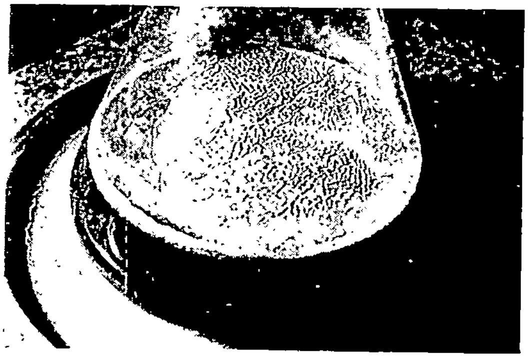

Fig. 1. *Saccharomyces aceti* strain *VT* 12–1, film on red wine after 25 days at room temperature

The same basal medium with 1 per cent of methanol showed, after 24 days, a slight growth, but it remained neutral and only a thin incomplete pellicle was formed. The cells of this pellicle were almost exclusively asci with one, two, three and four smooth, round ascospores (Fig. 2). *iso*Propanol is also oxidatively assimilated, with the production of acetone.

The culture can ferment glucose only; it can assimilate galactose, sucrose, maltose and lactose, but the assimilation is weak and in every case a thin pellicle is formed in which there are many asci. In malt extract broth, no pellicle is formed in three days at 25° C.

This organism is considered to be a new species in the genus *Saccharomyces*. The name *Saccharomyces aceti* is suggested. I have isolated two other strains of this species.

From a white wine of Montánchez (Cáceres, Spain) I have isolated another *Saccharomyces* strain, which also forms a film on white wine and on grape must after alcoholic fermentation. This strain shows a great resemblance to *Saccharomyces aceti* in its oxidizing properties, but it ferments glucose, saccharose and raffinose 1/3. I have isolated two other strains with the same properties, except for their sugar assimilation: the first of these three assimilated galactose and lactose weakly, the second assimilated maltose weakly, and the third did not assimilate galactose, maltose or lactose. I did not consider these differences important enough to differentiate these strains from the other one. These organisms are considered to be a new species in the genus *Saccharomyces*. The name *Saccharomyces oxidans* is suggested.

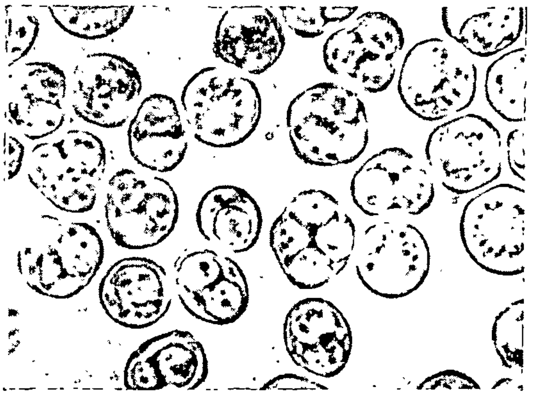

Fig. 2. *Saccharomyces aceti* strain *VT* 19–1. Asci with one, two, three and four spores. From the yeast nitrogen base of Wickerham with 1 per cent methanol, after 24 days at 25° C. Unstained. (× 1,750)

Cultures of *Saccharomyces aceti* and of *S. oxidans* have been deposited in the Yeast Collection of the Central Bureau voor Schimmelcultures in Delft.

A detailed account of this work, which was supported by a grant of the March Foundation, will be published elsewhere.

Analeptic Action of Anibine

Anibine, the alkaloid from the wood of the South American rosewood trees (*Aniba Duckei* Kostermans and *Aniba rosaeodora* Ducke), has been shown to be 4-methoxy-6-(3′-pyridyl)-α-pyrone[1].

Investigating the pharmacological properties of this substance, we found its action to be similar to that of nikethamide, with which it also shares certain structural features. In the present communication we wish to report on the analeptic action of anibine and compare its toxicity with that of nikethamide.

Solutions of both substances of equal concentration and acidity were used in the tests. Nikethamide is miscible with water. The solubility of anibine or even of its hydrochloride in water is small at room temperature. Solutions of 2 per cent anibine adjusted to *p*H 3·5 with hydrochloric acid, prepared by heating, were stable for some time at 37°. Distilled water, physiological salt solution or isotonic glucose solution were used indifferently as diluents without affecting the results of the tests.

Anibine and nikethamide produced the same toxic symptoms in albino mice of 20 gm. weight when 1 ml. of the 2 per cent solutions (20 mgm.) was injected. Intravenous injections resulted in immediate clonic convulsions, congestion and nasal hæmorrhage followed by death. These symptoms were somewhat delayed if the injections were applied intraperitoneally. Intravenous injections of 0·5 ml. (10 mgm.) produced the same symptoms, even if at a slower rate, death following after 20–25 min. Intraperitoneal injections of 0·5 ml. of the 2 per cent solutions showed the difference in toxicity of the two substances. Animals injected with the solution of nikethamide suffered prolonged convulsions without lethal result during 1 hr.; animals injected with the solution of anibine did not show any disturbance.

Tests of analeptic action were carried out on male rabbits, weighing approximately 2 kgm., using solu-

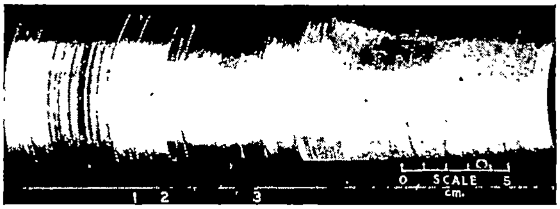

Fig. 1. Respiration record (pressure variation at the trachea) of a male rabbit, weighing 1·8 kgm., which remained without anæsthesia during the test (1 cm. on the abscissa = 1 min.). (1) Respiration-rate at the start, 100 per min. (2) Jugular injection of 12 mgm. of morphine hydrochloride: the respiration-rate fell to 75 per min. and the amplitude of breathing diminished. (3) Jugular injection of 20 mgm. of anibine in 1 ml. of isotonic glucose solution at 37°: the rate rose to 120 per min. and the amplitude increased

tions of different concentrations and recording graphically the effect upon breathing and arterial pressure. Intravenous injections of 0·5 ml. of 0·1 and 0·2 per cent solutions of anibine reduced slightly the arterial pressure. Higher doses (1 ml. of 2 per cent solution of anibine) produced a marked analeptic effect on animals the respiratory centres of which had been previously depressed by morphine (Fig. 1). Blank tests in which only the diluents, at the same pH, were injected failed to affect respiration.

Indole-3-aldehyde from Tissues

Salhanick and Berliner[1] studied a feminizing adrenal tumour from a man of 22. It weighed 920 gm., of which 523 gm. were used for chemical extraction. The frozen tissue was homogenized and extracted with acetone, leaving a 'protein' residue. The aqueous acetone was extracted with chloroform and the resulting lipid was partitioned between hexane and 75 per cent methanol. The latter was reduced to small bulk and extracted with chloroform to yield 0·67 gm. of yellow oil. The protein residue was digested with alkali (1 l. 5 per cent sodium hydroxide) for two days and extracted first with ether at pH 10 and then at pH 3 after acidification. After partitioning the extract, 0·26 gm. of oil was obtained. Chromatography on silica gel yielded progesterone, equilenin and two unidentified materials designated *AAE-I-BI* (44 μgm.) and *AAE-I-AI* (23 μgm.) from the acetone extract. From the protein hydrolysate extract the same materials were obtained in somewhat larger amounts (*AAE-I-AI*, 109 μgm.) together with three further unidentified fractions.

Substance *AAE-I-AI* showed (in methanol) absorption peaks at 242, 260 and 295 mμ and in concentrated sulphuric acid peaks at 240, 265 and 330 mμ. The published absorption curves show well-marked patterns of maxima and minima. The preparation exhibited a positive Millon test, regarded as indicative of a 3 : 5-unsubstituted hydroxyphenyl group ; it also gave a positive Zimmermann reaction for 17-ketosteroid. The total amount of material (132 μgm.) was very small, and there was no evidence as to purity. It was uncertain whether the chemical tests and the spectrophotometric characteristics were due to a single compound.

There can now, however, be little doubt that the spectroscopically recognizable constituent of *AAE-I-AI* was indole-3-aldehyde (Table 1) or a chromophorically identical substance.

The most surprising feature of the properties of the aldehyde is the change in absorption spectra in the presence of alkali.

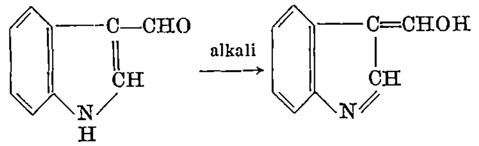
The indole nucleus shows an intense absorption band near 220–225 mμ and a region of weaker selective absorption around 270–280 mμ (order 10,000) with some fine structure. This applies to indole, 2-methyl-, 3-methyl- and 7-methyl-indole as well as to indole-3-acetic acid and tryptophan. Addition of sodium ethoxide to ethanolic solutions effects no marked change.

Table 1. Properties of Indole-3-aldehyde (Formylindole)

Solvent*	$\lambda_{max.}$ (mμ)	$\epsilon_{max.}$	$\lambda_{min.}$ (mμ)	$\epsilon_{min.}$
Ethanol	242	13,700	227	4,700
	260	11,700	252	11,000
	296	13,440	272	7,200
Ethanolic sodium ethoxide (0·1 *M*)	266	19,900	237	2,500
	326	20,400	293	5,850
Concentrated sulphuric acid	235	28,800	220	17,900
	266	54,200	250	28,700
	329	46,700	285	10,100

* See also G. F. Smith (ref. 2) for aqueous and aqueous alkaline solutions.

The new effect with indole-3-aldehyde has been attributed to the change :



In fact, we have found that there is an equilibrium which varies with the pH.

Indole-3-aldehyde has also been shown[3] to be one of the photochemical products of the irradiation of indole-3-acetic acid with light of wave-length 280 mμ.

In the course of an extended study of tissue unsaponifiable fractions we have noted a material (fraction *SF*) showing $\lambda_{max.}$ 235 and 282 mμ (in *cyclo*hexane) and $\lambda_{max.}$ 242 and 295 mμ (inflexion 260 mμ in ethanol). Among the best sources of this material were pancreas and spleen from several species. By chromatography on alumina the E(1 per cent, 1 cm., 282 mμ) value was raised to 50 and at that stage a small quantity was subjected to molecular distillation and yielded a few mgm. of white crystals. The absorption curves for this preparation in ethanol and in sulphuric acid reproduced those of *AAE-I-AI* but the chemical constitution remained unknown. The crystals gave a negative Millon reaction and a positive Tollens reaction. Small amounts of molecular distillates were kindly examined for us in the mass spectrograph at the Thornton Research Laboratories of Shell, Ltd. Mr. A. Quayle and his colleagues (to whom we are much indebted) found in the purer preparation evidence that the largest particles were of mass number (molecular weight) 144 and 145 and with nitrogen present it was suggested that an indole derivative was possible. Examination of authentic indole-3-aldehyde soon confirmed the nature of the selectively absorbing substance. It is perhaps too early to discuss in detail the significance of the detection of indole-3-aldehyde in the adrenal tumour, in normal pancreas and spleen and in the photoproducts of indole-3-acetic acid. The idea that it is a straightforward artefact derived from the tryptophan of proteins is not consistent with the evidence.

Effect of Vitamin B Complex on the Teratogenic Activity of Hypervitaminosis A

Some years ago, attention was directed by Cohlan[1] to the teratogenic effects of large doses of vitamin A administered to laboratory animals during pregnancy. His observations have since been fully confirmed by a number of workers.

Recently, it has been shown that the teratogenic activity of hypervitaminosis A can be modified by the concurrent administration of other substances. In particular, it has been observed that cortisone and 4-methyl-2-thiouracil augment or potentiate the teratogenic action, whereas insulin tends to diminish it[2].

Among the commonest malformations of the young induced by maternal hypervitaminosis A are cleft palate and deformities of the brain and skull such as exencephaly and hydrocephaly. Maternal deficiencies in vitamins of the B complex have also been shown experimentally to result in the production of similar fœtal anomalies[3].

Suggestions have been made from time to time that the effect of hypervitaminosis A in animals is to produce a 'displacement deficiency' in the B group of vitamins[4]. Accordingly, it was decided to investigate the possibility that the concurrent administration of the B vitamins in large doses might mitigate the teratogenic effects of hypervitaminosis A. In the experiments reported here a 'blunderbuss' injection of B vitamins was employed as a preliminary to an examination of the effects of individual vitamins of the B group.

Female rats of the Wistar strain were used as in the experiments reported previously. Vitamin D (2,000 i.u.) and 50 mgm. vitamin E were given by mouth at the beginning of the experiment. After mating with normal male rats, pregnancy was determined by the presence of spermatozoa in the vagina. One group of pregnant female rats received 40,000 i.u. vitamin A acetate daily by gastric intubation from the eighth to thirteenth days of pregnancy. A second group received 40,000 i.u. vitamin A daily and, in addition, 0·5 ml. vitamin B complex by subcutaneous injection from the eighth to thirteenth days. The B injection contained aneurine hydrochloride 25 mgm., nicotinamide 16 mgm., riboflavin 0·4 mgm., pyridoxine hydrochloride 5 mgm. in benzyl alcohol, 14 mgm., as a vehicle.

The rats were killed on the twentieth day of pregnancy and the young removed for examination. Only gross deformities involving the brain or palate were considered.

In the group of rats which received vitamin A alone, 9 young out of 121 showed deformities of the brain, an incidence of 7·4 per cent. No young with deformities of the brain were encountered among the young from the groups which received both vitamin A and vitamin B complex. The results of the experiment in relation to malformations of the palate are shown in Table 1. It will be noted that when vitamin A alone was given, 31·4 per cent of the young showed clefts of the palate, whereas when vitamins of the B group were given in addition only one of the young had a cleft palate, an incidence of 1·5 per cent.

It seems reasonable from these experiments to reach the tentative conclusion that the failure of vitamin A to produce a comparable incidence of malformations in the two groups was due to the presence, in the second group of animals, of a large amount of vitamins of the B group. Further experiments are in progress with the view of determining whether the protective effect requires the presence of a number of B vitamins or is mediated by a single member of the group.

Table 1

Treatment	No. of rats	Total No. of young	No. of young with cleft palate	Percentage of young with cleft palate
Vitamin A	16	121	38	31·4
Vitamin A Vitamin B	9	65	1	1·5

The hypothesis that it is the relative balance between the amounts of different vitamins which is critical for normal development receives some additional support from these experiments. Furthermore, the results are not discordant with the view that an excess of vitamin A may produce a degree of vitamin B deficiency which can be compensated by the concurrent administration of this vitamin.

Ribonuclease and Deoxyribonuclease Activities during Normal and Neoplastic Growth

A relationship has been repeatedly demonstrated between the rate of growth of a tissue and its ribonuclease (RNase) and deoxyribonuclease (DNase) activities[1-4].

These findings stimulated the present investigation. The nucleic acid content and nuclease activities of a number of human and animal malignant tumours have been determined. The determinations were carried out as described earlier[1 2]. Except in the case of the Ehrlich ascites tumour the tissues of origin have also been examined.

The results are summarized in Table 1. As in previous papers[1-3] enzyme activities are expressed relative to deoxyribonucleic acid–phosphorus content. In some tumours the ribonuclease activity was equal to that in the tissue of origin; in others it was lower. Only in pancreatic carcinoma was there an increase. Ledoux *et al.*[5] have recently reported that in human cervical cancer the ratio of acid ribonuclease activity to ribonucleic acid content is lower than in the normal tissue of origin. Accordingly, the corresponding ratios have been calculated for the tissues examined in the present experiments (Table 1). Two of the tumours gave results which support Ledoux's concept: the Ehrlich ascites carcinoma, which contained no measurable ribonuclease; and one case of stomach carcinoma in which the ribonuclease/ribonucleic acid ratio, although high, was significantly lower than the ratio given by the gastric mucosa of the same patient.

Table 1. Nucleic Acid Content and Nuclease Activities in Normal and Neoplastic Tissues

* Ribonuclease activities determined by incubating tissue breis with ribonucleic acid at pH 7·70, adding trichloracetic acid–lanthanum acetate, centrifuging and reading the optical density in the supernatant against the appropriate blank. The activities are expressed as optical density increase/hr./μgm. tissue deoxyribonucleic acid–phosphorus or ribonucleic acid–phosphorus (DNAP or RNAP).

† Deoxyribonuclease activities determined by incubating tissue breis with deoxyribonucleic acid at pH 5·25 and following the procedure above. The increase in deoxypentose in the supernatant was determined colorimetrically and from this the amount of deoxyribonucleic acid–phosphorus was calculated. The deoxyribonuclease activities are expressed as deoxyribonucleic acid–phosphorus liberated per hr./μgm. tissue deoxyribonucleic acid–phosphorus.

‡ Dimethylbenzanthracene tumour. These have been studied by Scholler *et al.* (ref. 8). They were obtained through the courtesy of Dr. Jean Scholler.

In the other tumours the ratio was equal to or greater than that of the tissue of origin. It therefore appears that a diminished alkaline ribonuclease/ribonucleic acid ratio is not characteristic of all tumours.

In general, the deoxyribonuclease activities of the neoplastic tissues studied did not differ greatly from those of the tissue of origin. The only exception was a hepatic carcinoma which had a deoxyribonuclease activity only 25–30 per cent that of liver.

Although the growth-rates of neoplastic tissues differ within wide limits, they usually grow faster than their tissues of origin. The incorporation of isotopes into various cellular constituents, in particular into the nucleic acids, also occurs at higher rates in tumours than in their tissues of origin[6]. In this respect there is a similarity between rapidly growing non-malignant and neoplastic tissues. The synthetic activities as reflected by the rate of isotope incorporation are apparently stimulated in both types of growth. The ribonuclease and deoxyribonuclease activities, on the other hand, show completely different patterns in normal and neoplastic growth. Whereas the normal tissue response to a growth stimulus involves a sharp increase in the activities of these enzymes, neoplastic tissues do not seem to respond in this way.

There has been some speculation on the role of the nucleases in the synthesis or degradation of nucleic acids *in vivo*. There is a positive correlation between the activities of these enzymes and the rate of isotope incorporation into the nucleic acids during the non-malignant growth[4] in regenerating liver. This suggests a synthetic activity. The lack of correlation, however, which is found during neoplastic growth argues against this interpretation. It is more likely that they have a degradative or regulatory function. The parallelism in normal growth between nuclease activities and the rate of isotope incorporation into the nucleic acids contrasts sharply with the absence of such a relationship during neoplastic growth. During normal growth the synthetic activities[7] seem counterbalanced by the ribonuclease and deoxyribonuclease activities, whereas in neoplastic growth there appears to be an imbalance between these systems. The events during carcinogenesis leading to this state are now the subject of investigation in this laboratory and a report will shortly be published.

We wish to thank Dr. Alexander Brunschwig for kindly supplying us with operative specimens, and Dr. George Bosworth Brown for his encouragement and interest. We wish to acknowledge a grant from the American Cancer Society and the Swedish Cancer Society to Dr. Sam Brody. This investigation was supported in part by funds from the American Cancer Society, National Cancer Institute, National Institutes of Health, Public Health Service (Grant *CY*–3190), and from the Atomic Energy Commission (Contract No. *AT*(30–1)–910).

Physical Reactivity of Liver and Brain Cortex Mitochondria

In recent investigations[1] we found that rat brain cortex mitochondria, isolated in 0·25 M sucrose by method II of Brody and Bain[2], had, in the same experimental conditions, certain physical properties different from those of rat liver mitochondria isolated by the method of Myers and Slater[3]. The incorporation of 0·01 M ethylenediaminetetraacetate in the 0·25 M sucrose, used by Slater[4] in the preparation and stabilization of heart sarcosomes, has yielded some results concerning the apparent stability of brain granules at 25° C. The ethylenediaminetetraacetate used was the disodium salt, brought to pH 7·5 with potassium hydroxide, and the solution was made up with de-ionized water. Experiments were performed with mitochondria isolated from the liver and the brain cortex of normal white rats (Wistar strain), three months old. The tissues were

* The percentage number was − 27 at 16 min.

rapidly homogenized in a Potter–Elvehjem homogenizer fitted with a 'Teflon' pestle, with ten volumes of the sucrose–ethylenediaminetetraacetate medium. Nuclei, erythrocytes, intact cells and debris were sedimented by centrifugation at 700*g* for 10 min., and the mitochondria then separated by centrifugation of the supernatant fluid at 8,500*g* for 10 min. (rate controlled by an electronic stroboscope, Philips *PR* 9103). The mitochondria were washed by resuspension and resedimentation in the same conditions. The final pellets were suspended in the sucrose–ethylenediaminetetraacetate medium, so that the mitochondria from 0·80 gm. of fresh liver or from 0·90 gm. of fresh brain cortex were suspended in 1·0 ml. All operations were carried out at 0° C. The purity of isolated fractions was controlled morphologically with phase microscopy and chemically by the colorimetric test of Potter, Recknagel and Hurlbert[5] (reduction of janus green *B* to yield diethylsafranine at 37° C.). The mitochondria were used immediately following their isolation. Mitochondrial volume changes were studied at 25° C. by following the optical density of suspensions at 550 mμ, in 1-cm. cells, with a Meunier photometer (Jobin and Yvon, Arcueil), as described by Cleland[6]. The basic test system (volume 7 ml.) contained mitochondria (about 0·03 ml. of the stock suspension, giving an initial optical density of approximately 0·300) suspended in 0·05 M sucrose and 0·01 M *tris* (hydroxymethyl) aminomethane, *p*H 7·4; the solution was made up in de-ionized water. The first reading was taken 30 sec. after the addition of the mitochondria and subsequent readings at 2-min. intervals for 10 min.; the zero-time value was obtained by extrapolation.

Table 1 and Fig. 1 show that the addition of 0·01 M ethylenediaminetetraacetate to the isotonic sucrose medium during the preparation of mitochondria provided liver granules which were very stable when tested in the hypotonic sucrose medium, in complete agreement with earlier results[7]; the brain granules, however, swelled rapidly. On the other hand, the swelling of brain mitochondria was largely prevented by calcium ions; in contrast, these ions at the same concentration (10^{-3} M) produced rapid swelling in liver mitochondria. Magnesium ions also prevented the swelling of brain granules, but had no effect on the stability of liver granules.

As pointed out by Slater[4], it might be expected that the addition of the chelating agent ethylenediaminetetraacetate to the isolation medium would remove essential metals from the mitochondria, as well as prevent the binding of calcium ions by the granules. Christie, Judah and Rees[8] concluded that cobalt activates and stabilizes respiration in brain mitochondria treated with certain chelating agents (but not ethylenediaminetetraacetate). Table 1

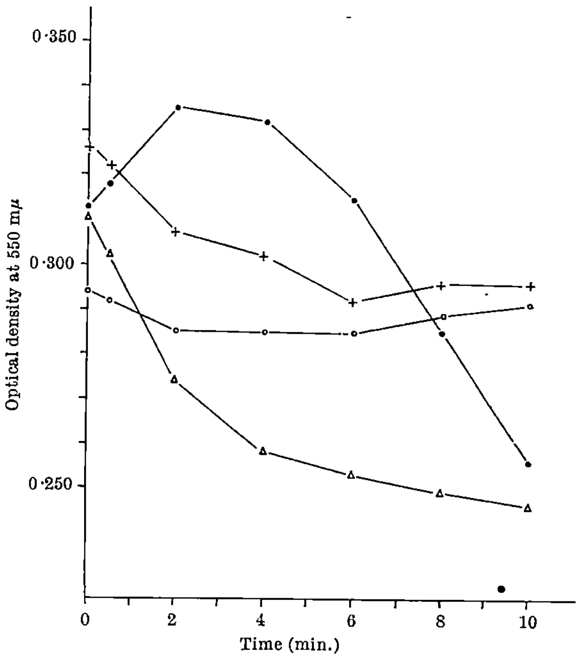

Fig. 1. Influence of the method of isolation on the degree of swelling of rat liver and brain cortex mitochondria. The test medium contained 0·05 M sucrose and 0·01 M *tris* buffer *p*H 7·4, at 25° C. Liver (●—●) and brain cortex (+—+) mitochondria isolated in 0·25 M sucrose. Liver (○—○) and brain cortex (△—△) mitochondria isolated in 0·25 M sucrose + 0·01 M ethylenediaminetetraacetate

shows that cobalt ions (10^{-5} M) did not affect the swelling of brain granules. On the other hand, Slater[4] supposed that ethylenediaminetetraacetate would also activate sensitive —SH enzymes by removing contaminating heavy metals. In Table 1 we see that mercuric and argentic (Ag^{++}) ions had no effect on the swelling of brain mitochondria; mercuric ions had a slight preventive effect on liver mitochondria.

Hunter and Ford[7] considered the protective effect of ethylenediaminetetraacetate against pre-incubation of liver mitochondria with phosphate to be completely unexpected. Our results (Table 1) confirm earlier ones but in contrast phosphate had a slight preventive action on the swelling of brain mitochondria. Numerous authors[4,7,9] established that adenosine triphosphate had a strong preventive effect on the swelling of liver mitochondria, heart sarcosomes and cytoplasmic granules of diverse tissues. In this paper we confirm our earlier results[1]: adenosine triphosphate, at a concentration of 10^{-3} M, had no preventive effect on the swelling of brain cortex mitochondria isolated in the sucrose–ethylenediaminetetraacetate medium.

Berger[10] concluded that the different sensitivity of the mitochondria of liver and brain tissues towards chlorpromazine is determined rather by the structural differences than by some intrinsic differences in metabolic pattern: brain mitochondria has a greater adsorption capacity than liver mitochondria. This capacity was confirmed recently by Kunz[11], who has shown that, in contrast to rat liver mitochondria, brain granules do not require the addition of magnesium ions for the oxidative decarboxylation of pyruvate. Our preliminary results support the view that the so-called membrane of the brain mitochondria possesses a specific structure which confers a high physical stability on these granules.

This work will be continued and will be published in full elsewhere.

Identification of Meprobamate by Adsorption Chromatography on Chromatoplates

Methods have recently been proposed (refs. 1 and 2 and Walkenstein, S., Knebel, C., MacMullen, J., and Seifter, J., private communication) for the identification and quantitative determination of 2-methyl-2-*n*-propyl-1,3-propanediol dicarbamate (meprobamate) in blood and urine. These methods are sensitive and practical but appear to be insufficiently specific for use in analytical toxicology.

Paper chromatography was employed by Riebeling[3] for the detection of meprobamate combined with glycuronic acid in urine, but only the glycuronic acid is in fact detected by this method. Applications of paper chromatography to the separation and identification of meprobamate are very difficult because the compound is insoluble in water and because there are no methods for detecting the spots.

We have successfully employed a method for identifying meprobamate, based on adsorption chromatography on chromatoplates.

Chromatoplates were prepared using Demole's[4] modification of Reitsema's method[5]. 54 ml. of distilled water is added to a mixture of 28·5 gm. of pure silicic acid and 1·5 gm. of rice starch. The suspension is heated over a flame almost to boiling point to obtain a thick paste which is then diluted with 20–30 ml. of water and again heated to the same temperature for some minutes. After cooling, 10 ml. of the suspension is poured into the centre of a glass plate 17 cm. × 11 cm. × 0·2 cm. The liquid is quickly distributed on the surface with a spatula, and the layer is made homogeneous by rapid transverse movements of the plate.

Chromatoplates are left to dry for a few hours at room temperature and are then activated by heating in an oven for 30 min. at 100–105° C. The chromatoplates so prepared are stored in desiccators with anhydrous calcium chloride.

Meprobamate is isolated from urine by adding 0·2 ml. of N sodium hydroxide and 10 ml. of ether to 5 ml. of urine in a glass-stoppered centrifuge tube.

After shaking, the tube is centrifuged, the ether is decanted, and 60 mgm. of charcoal is added. This mixture is again shaken, filtered and evaporated to dryness under a stream of air. The dry residue is dissolved in 0·1 ml. of ethyl alcohol and known amounts of the alcoholic solution are quickly spotted on the starting line of the chromatoplate under a stream of hot air. The spotting of the plates inside the desiccator, as suggested by Demole[4], was found to be unnecessary for routine work.

Ascending development is carried out in a glass jar with cyclohexane and absolute ethyl alcohol (85 : 15) as solvent. After development for about 2 hr., when the solvent is 10–11 cm. from the starting line, the chromatoplate is removed, dried at room temperature and sprayed lightly with concen-

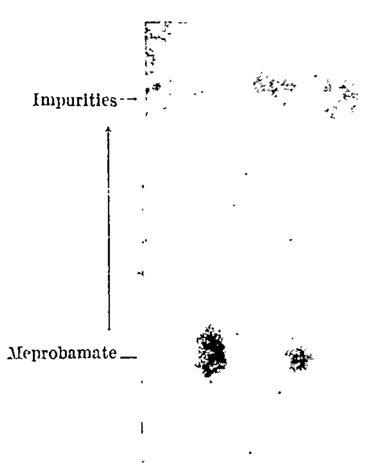

Fig. 1

trated sulphuric acid. A suitable sprayer bottle is described by Kirchner *et al.*[6]. The plate is then heated in an oven at 110–115° C. for 2–3 min., sprayed lightly with distilled water and reheated as before for some minutes, until yellow spots of meprobamate appear. Overheating should be avoided to prevent darkening of the chromatoplates. The spots, which disappear in about a day, have R_F 0·30. Exact R_F values are obtained only in the central zone of the chromatograms; at the periphery of the plates R_F values are higher, due to the border effect. Unidentified impurities migrate with the solvent front (Fig. 1) and become violet under the sulphuric acid treatment.

A quantitative determination can be easily made by cutting out the spot and transferring it to a test tube. 1 ml. of distilled water is added, and then after careful shaking, 1 ml. of a 0·2 per cent hydroquinone in concentrated sulphuric acid[3]. The test tube is then heated in a boiling water bath for 20 min., till a yellow colour is obtained; this has an absorption maximum at 420 mμ and can therefore be determined spectrophotometrically.

Further details will be published elsewhere.

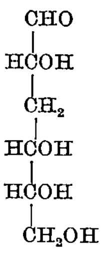
Synthesis of 3,6-Dideoxy-D-*ribo*-hexose (3,6-Dideoxy-D-glucose) and its Identification with Paratose

3,6-DIDEOXY-HEXOSES are a new class of natural sugars; five members of this group are known at present: abequose[1], tyvelose[1,2], paratose[3] and colitose[4] have been found in specific polysaccharides extracted from various species of *Salmonella*, and ascarylose is obtained by hydrolysis of three glycolipids (the ascarosides *A*, *B* and *C*) extracted from the egg membrane and the cuticle of *Parascaris equorum*[5]. We have shown that all these sugars are 3,6-dideoxy-hexoses[6,7].

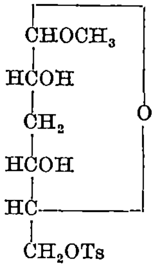
In a recent paper[8], we reported the synthesis of 3,6-dideoxy-D-*xylo*-hexose (3,6-dideoxy-D-galactose) and 3,6-dideoxy-D-*arabino*-hexose (3,6-dideoxy-D-mannose) and showed that the first is identical with abequose and the second with tyvelose, while colitose is the optical antipode of abequose and ascarylose is the optical antipode of tyvelose.

We now report the synthesis of 3,6-dideoxy-D-*ribo*-hexose (3,6-dideoxy-D-glucose) (III) and its identification with paratose.

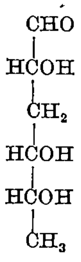
3,6-Dideoxy-D-*ribo*-hexose (3,6-dideoxy-D-glucose) (III) was synthesized starting from 3-deoxy-D-*ribo*-hexose (3-deoxy-D-glucose) (I) kindly supplied by Drs. J. W. Pratt and N. K. Richtmyer[9]; the methylglucoside of this compound was tosylated, and after chromatography on magnesium silicate the methyl 3-deoxy-6-tosyl-D-*ribo*-hexoside (II) was obtained as a colourless syrup which was reduced by lithium aluminium hydride in a mixture of ether and benzene (1 : 1). After the usual treatment the methyl 3,6-dideoxy-D-*ribo*-hexoside was extracted with chloroform, the extract hydrolysed with 0·1 *N* hydrochloric acid in boiling water, and the free sugar then chromatographed on a column of Whatman cellulose powder. After elution of the sugar (II) with acetone/water (95 : 5) it was distilled at 0·05 mm. and obtained as a colourless syrup, $[\alpha]_D + 10 \pm 2°$; R_F 0·71 in butanol/pyridine/water (6 : 4 : 3); calculated for $C_6H_{12}O_4$: C, 48·64; H, 8·16 per cent; found: C, 48·68; H, 8·23 per cent.



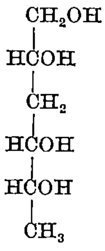
I



II



III



IV

The corresponding hexitol (IV) was prepared by reduction with sodium borohydride in water and obtained as crystals after distillation at 0·05 mm. After recrystallization from acetone, 3,6-dideoxy-D-*ribo*-hexitol (IV) was obtained as colourless needles, melting at 67–68°; $[\alpha]_D$ −18 ± 2°; R_F 0·53 in butanol/pyridine/water (6 : 4 : 3); calculated for $C_6H_{14}O_4$: C, 47·98; H, 9·40 per cent; found: C, 47·93; H, 9·68 per cent.

Paratose, which has recently been isolated by Davies *et al.*[3] from a polysaccharide of *Salmonella paratyphi A*, is a syrup, $[\alpha]_D + 8 \pm 2°$, and the hexitol (paratitol) obtained by reduction with sodium borohydride melts at 66–68° and has $[\alpha]_D - 16 \pm 2°$. (Found: C, 47·61; H, 9·52 per cent.)

The mixed melting point of paratitol and 3,6-dideoxy-D-*ribo*-hexitol (3,6-dideoxy-D-sorbitol) (IV) gave no depression. R_F values and infra-red spectra of both paratose and the crystalline hexitol are identical with those of the respective synthetic compounds.

Beta-globulin Polymorphism in Cattle, Sheep and Goats

Detection by paper electrophoresis. Using starch gel electrophoresis, six cattle[1], fourteen sheep[2], three goat (see later) and three human[3,4] β-globulin phenotypes have been recognized and indicated to be under the genetic control of three, five, two and three allelomorphs respectively. As one of us had noticed a variation in the number and position of the β-globulin zones in paper electrophoresis of animal sera, the two methods have been compared on sera from cattle, sheep and goats. Starch gel electrophoresis was carried out in phosphate buffer[1] *p*H 7·6, paper electrophoresis on a wide strip of horizontally suspended Whatman 3*MM* paper in barbiturate buffer *p*H 8·6, *I* 0·05. Typical examples of corresponding electropherograms of sheep and cattle sera are shown in Figs. 1 and 2. The electropherograms of goat sera shown in Fig. 3 are discussed below.

Table 1. OBSERVED AND EXPECTED DISTRIBUTION OF OFFSPRING PHENOTYPES FROM GOAT β-GLOBULIN MATINGS

Mating	Offspring β^{AA} Obs.	Exp.	β^{AB} Obs.	Exp.	β^{BB} Obs.	Exp.
$\beta^{AA} \times \beta^{AA}$	No matings					
$\beta^{AA} \times \beta^{AB}$	8	8·5	9	8·5	0	0
$\beta^{AA} \times \beta^{BB}$	0	0	9	9	0	0
$\beta^{AB} \times \beta^{AB}$	1	0·75	1	1·5	1	0·75
$\beta^{AB} \times \beta^{BB}$	0	0	4	5·5	7	5·5
$\beta^{BB} \times \beta^{BB}$	No matings					

It is evident that the different phenotypes in these animals can be distinguished by paper electrophoresis on the basis of β-globulin components of different mobilities. In the simple phenotype system observed in goats (see later), paper electrophoresis was in fact used successfully for independent typing of the sera. From an observation of Smithies[3], it seems likely that human phenotypes could be distinguished on paper also.

Consideration of the electropherograms of homozygous sera shows that each β-globulin zone on paper corresponds to a group of zones in starch-gel electrophoresis, the number of zones in the group depending on the species. In sheep and goats there is a faint zone followed by an intensely staining zone, whereas in cattle there is a faint zone followed by a moderately staining zone and two intensely staining zones, described in order of decreasing mobility in the gel.

Comparison of the electropherograms of homozygous and heterozygous sera shows that some of the zones into which the β-globulin components are resolved in starch gel are superimposed in some of the heterozygous sera, particularly in cattle. When this occurs, resolution by paper electrophoresis becomes incomplete and the β-globulins usually appear as a broad zone. This superimposition also makes it difficult to apply a system of nomenclature based on individual coding of the starch gel zones[5] without knowing more about the resolving mechanism and interrelations of the zones in starch gel[6].

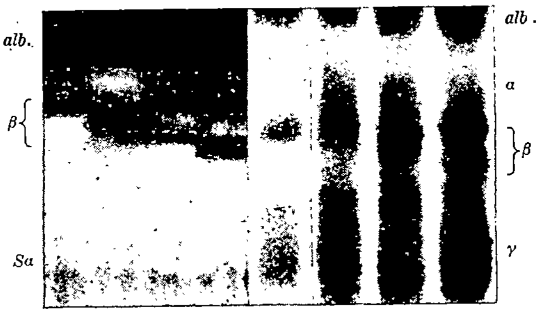

Fig. 1. Electropherograms of sheep sera showing β-globulins of sheep sera of four different phenotypes. Left, starch gel; right, paper electrophoresis. Key: α, β and γ = α-, β- and γ-globulins. *alb.*, albumin; *Sa*, slow alpha zone

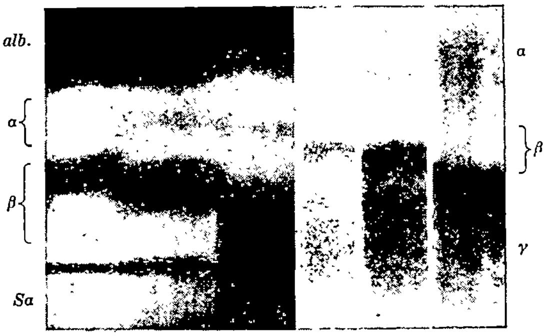

Fig. 2. Electropherograms showing β-globulins of three homozygous cattle sera. Left, starch gel; right, paper electrophoresis. Key: as Fig. 1

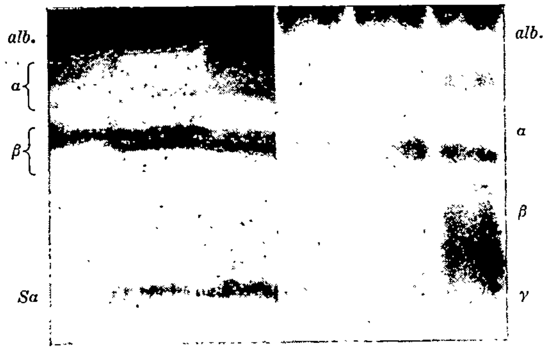

Fig. 3. Electropherograms of goat β-globulin phenotypes. Left, starch gel; right, paper electrophoresis. In each case the phenotypes are from left to right β^{AA}, β^{AB} and β^{BB}. Key: as Fig. 1

β-*Globulin polymorphism of goats.* Sera from about sixty goats of the British Saanan breed at the Rowett Research Institute have been examined by starch gel electrophoresis using phosphate buffer[1] and by paper electrophoresis. This revealed three phenotypes shown in the electropherograms of Fig. 3. (The two methods are compared above.)

Some animals were examined twice with intervals of up to a year and the phenotype found to be constant. It was also found that mixed sera of the two outermost phenotypes shown in Fig. 3 were indistinguishable from the third (centre) when run together in starch gel. This suggested that the β-globulins of goats are controlled by two allelomorphs β^A and β^B, giving rise to the genotypes β^A/β^A, β^A/β^B and β^B/β^B, and the three phenotypes β^{AA}, β^{AB} and β^{BB}. This hypothesis is supported by mating results shown in Table 1, where the observed and expected distribution of phenotypes of some forty offspring are compared.

This genetic mechanism is similar to that proposed for β-globulin polymorphism in cattle, sheep and man.

Structure of Cardiolipin

Pangborn[1] considered that the glycerylglycerophosphate skeleton of cardiolipin contained three phosphoric acid and four glycerol residues (I), the six available hydroxyl groups in this structure being esterified with unsaturated fatty acids in the intact phospholipid.

$$\text{(I) } CH_2OH.CHOH.CH_2O.P : O(OH).CH_2O.CHOH.CH_2O.P : O(OH).CH_2O.CHOH.CH_2O.P : O(OH).CH_2O.CHOH.CH_2OH$$

Macfarlane and Gray[2] suggested a simpler structure for cardiolipin of two phosphoric acid, three glycerol and four fatty acid residues, with a free hydroxyl group on one of the glycerol residues. Evidence in favour of this structure has been obtained by oxidative degradation of the deacylated polyglycerophosphate.

Cardiolipin, prepared from ox heart by the method of Faure and Morelec-Coulon[3], was saponified in 1 per cent ethanolic potassium hydroxide at 20° for 4 hr. The phosphorus was recovered as the potassium salt, insoluble in ethanol, of the polyglycerophosphate (orthophosphate nil; phosphomonoester by enzymic assay nil). The ester was treated in aqueous solution with 50 per cent excess of sodium periodate at 20° for 30 min., and the formaldehyde produced was estimated colorimetrically with chromotropic acid; found, molar ratio formaldehyde : phosphorus, 1·03 : 1·0. The iodates were removed as the insoluble barium salts and the formaldehyde by repeated evaporation of the solution to dryness in a vacuum desiccator. The phosphorus was recovered as the soluble barium salt of a complex ester (orthophosphate and phosphomonoester, nil). The aldehyde content of the ester was estimated by oxidation with hypoiodite by the method of Macleod and Robison[4]; found, 0·87 mole aldehyde/mole phosphorus. The results indicate that the polyglycerophosphate skeleton of cardiolipin consists of three glycerol residues linked by two phosphoric acid residues (II); on oxidation of the terminal glycerol residues with periodate II would give 2 moles of formaldehyde and glyceroldi-(formylmethyl hydrogen phosphate) (III). The ester linkages are assigned arbitrarily to the α position.

$$CH_2OH.CHOH.CH_2O.P : O(OH).CH_2O.CHOH.CH_2O.P : O(OH)CH_2O.CHOH.CH_2OH \quad \text{(II)} \rightarrow$$
$$CHO.CH_2O.P : O(OH).CH_2O.CHOH.CH_2O.P : O(OH).CH_2O.CHO \quad \text{(III)}$$
$$+2H.CHO$$

Different Types of Hæmoglobin in Two Strains of Mice

While studying the therapeutic effect of homologous bone marrow transplantation in irradiated mice we needed a simple and sensitive technique to differentiate between the hæmatopoietic activity of the host and that of the graft. The possibility of employing differences between the hæmoglobins of our two strains of mice (*CBA* and *C57BL*) and their hybrid was suggested by the findings of Ranney *et al.*[1,2], who demonstrated two different hæmoglobin patterns in eight inbred strains of mice by using paper electrophoresis.

In the present paper the results are described of two kinds of experiments on hæmoglobin, namely, electrophoresis in agar gel and denaturation with alkali.

Agar gel electrophoresis was carried out as described by Robinson *et al.*[3] with some minor modifications. Glass plates, 82 × 82 mm., were carefully cleaned with chromic acid and provided with a coating by submerging them in 0·3 per cent agar and drying at 60° C.; 9 ml. of a 1 per cent solution of agar in 0·05 *M* citrate buffer *p*H 6·5 was poured on to each and allowed to solidify. Electrical contact between buffer vessels and the agar layer was made with filter paper strips, saturated with the citrate buffer. The hæmoglobin solutions were prepared by lysing the washed erythrocytes of 0·04 ml. of tail blood with 0·05 ml. of glass-distilled water for 15 min. at room temperature. Thereafter 0·05 ml. of citrate buffer was added and the stromata were

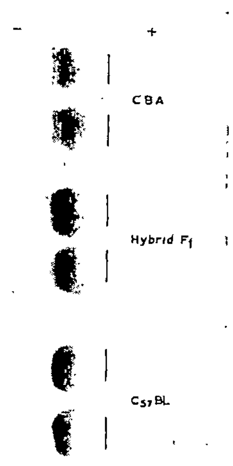

Fig. 1. Electrophoretic pattern of *CBA*, hybrid F_1 and *C57BL* mice

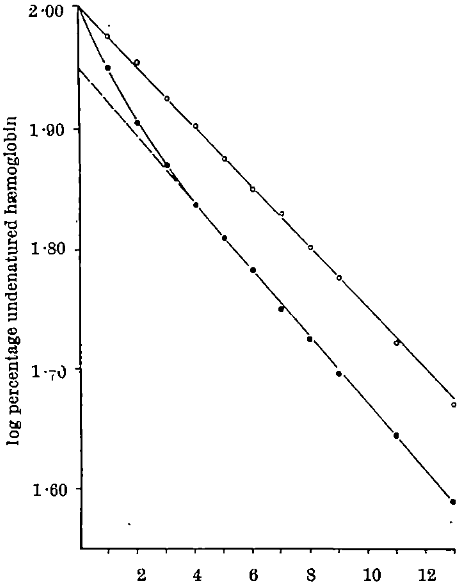

Fig. 2. Alkali denaturation of mouse hæmoglobin with 0·01 *N* sodium hydroxide. O—O—O, *C57BL* (mean of six); ●—●—●, *CBA* (mean of seven)

centrifuged down at 12,000 *g* (Servall centrifuge with the *SS*1-head, 9,600 r.p.m.). Electrophoresis was carried out in a cold chamber at 2° C., usually for 3–5 hours. The runs were made at 80 V., which resulted in a current of 19–21 m.amp. with one plate in our electrophoresis apparatus.

A typical electrophoretic pattern of mouse hæmoglobin is shown in Fig. 1, from which it may be concluded that hæmoglobin of *C57BL* mice has only one component, whereas hæmoglobin of *CBA* has two. The hæmoglobin of the hybrid F_1 (*CBA* ♂ × *C57BL* ♀) does not show a sharp boundary, but we have not been able to distinguish a second component. Recently, Dr. Mathé has informed us that a heterogeneity in the hæmoglobin of six strains of mice could be demonstrated by starch gel electrophoresis.

The alkali-denaturation velocity was measured as described by Jonxis and Visser[4] except that 0·01 *N* sodium hydroxide was used instead of 0·06 *N*, mouse hæmoglobin being much more labile to alkali than human hæmoglobin.

The results obtained with this method agree with those of the electrophoretic technique. On theoretical grounds it is to be expected that, for homogeneous hæmoglobin, the logarithm of the percentage denaturation is a linear function of time, whereas for heterogeneous hæmoglobin the function does not become linear until the more rapidly denatured component is totally converted[5]. This has been found to be the case, as may be seen from Fig. 2, which gives the denaturation curves for *C57BL* (mean of six determinations on different animals) and *CBA* mice (mean of seven). There is, however, a considerable variation in the slope of the curves for individual mice of the same strain, but the intersection of the linear part of the curves with the ordinates (percentage of slowly denatured component) gives significantly different values ($P < 0{\cdot}01$) for *C57BL*, *CBA* and hybrid F_1 mice respectively (Table 1).

Table 1. PERCENTAGE OF SLOWLY DENATURED COMPONENT OF *C57BL*-, *CBA*- AND HYBRID F_1 MOUSE HÆMOGLOBIN

Type of hæmoglobin	No. of experiments	Percentage of slowly denatured component ± *S.D.*
C57BL	6	100 ± 0·5
CBA	7	88 ± 0·7
Hybrid F_1	6	94 ± 0·8

Both methods have proved to be useful for the identification of the type of hæmoglobin in *CBA*-*C57BL* radiation chimæræ. The electrophoretic technique is preferable, because of its simplicity.

Different Heterogeneities of Mouse Hæmoglobin according to Strains

Two different electrophoretic hæmoglobin patterns have been demonstrated by paper electrophoresis in inbred strains of mice, and these have been shown to be under genetic control[1,2]. By means of moving-boundary electrophoresis, four different peaks have been observed in strains of genetically anæmic mice (ref. 3 and Cook, J. (personal communication) has observed three major peaks and two minor ones by chromatography on 'Amberlite *X*64'). In studies on two different strains of mice by electrophoresis in gelosis, Van Bekkum, D. W., and Welling, W. (personal communication), have demonstrated in one of them the existence of a single hæmoglobin component, and in the other the existence of several components. This communication describes the different patterns obtained by starch gel electrophoresis of hæmoglobins from six inbred strains of mice.

The strains were as follows: *C57Bl6*, *C57Br*, *AKR*, Swiss, *DBA*2 and *C3H*. Blood samples were drawn from several mice in each strain by puncture of the cavernous sinus. A 10 per cent hæmoglobin solution was prepared for immediate use by Drabkin's method[4] and stored at 4° C. Electrophoretic runs were performed within 24 hr. of the venous puncture, since the spontaneous denaturation of mouse hæmoglobin seems to be much faster than that of human hæmoglobin. Starch gels were prepared according to Smithies[5] and electrophoresis performed as described by de Grouchy *et al.*[6] (*p*H, 8·5 : 6 V./cm.; 5 hr.).

Table 1. THE FOUR TYPES OF HÆMOGLOBIN PATTERN OBSERVED IN SIX INBRED STRAINS OF MICE

	Description of pattern	Name of strains
Type 1 (Fig. 1*a*)	One very important major band. Two fringes, the more slowly moving one being slightly more important	*C57Bl6*
Type 2 (Fig. 1*b*)	Two major bands One minor slowly moving band	*AKR* *C3H*
Type 3 (Fig. 1*c*)	Three major fast moving bands One minor slowly moving band A certain number of *C57Br* did not exhibit one of the two slowly moving bands, thus, two sub-groups in type 3 may exist	*C57Br*
Type 4 (Fig. 1*d*)	Three major bands Two minor bands	Swiss *DBA*2

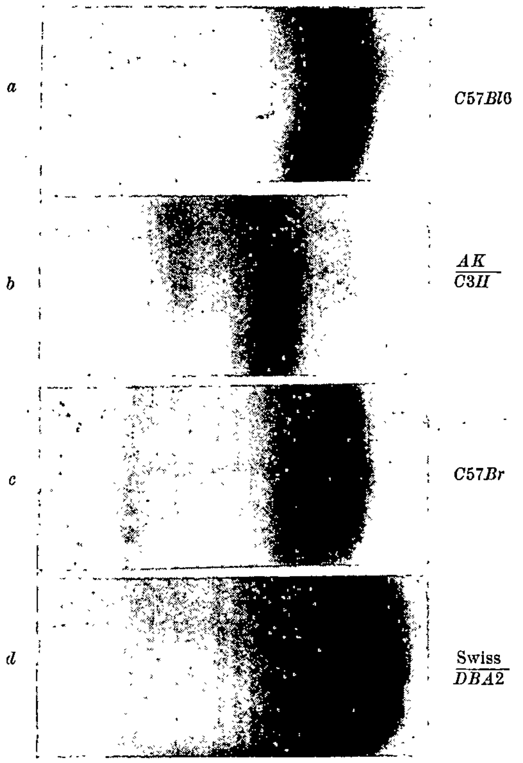

Fig. 1. Starch gel electrophoresis of mouse hæmoglobin. Four different patterns corresponding to different inbred strains

Electrophoretic patterns are characterized by a number of discrete bands which vary from one strain to another. The largest number of bands observed is five. It is thus possible to classify the seven strains of mice studied into four different groups according to their hæmoglobin pattern. Fig. 1 shows a typical pattern of each type and Table 1 is a summary of our results.

The high resolving power of starch gel electrophoresis permits the identification in mice of a larger number of hæmoglobin fractions than does paper electrophoresis or moving-boundary electrophoresis. Furthermore, it is possible to distinguish four different groups of inbred strains of mice, while only two were known previously.

Action of Plasmin on Cartilage

Much recent work[1-4] has shown that a considerable proportion of the chondroitin sulphate in the ground substance of cartilage is combined in some way or other with protein. It is possible that the relative ease with which the mucopolysaccharide can be obtained in a protein-free form[5] by extraction with mild alkali is a reflexion of the alkali lability of some of the protein-mucopolysaccharide bonds[4]. It is also known that papain and trypsin[2,4] lower the viscosity of solutions of chondroitin sulphate–protein complex and partially remove the proteins. Plasmin is a protease resulting from the activation of serum plasminogen by diverse means, including the action of the so-called kinases of streptococci[6] and staphylococci[7,8]. In view of the chondrolytic effects of joint infections caused by staphylococci and streptococci which produce kinases, in contrast to infection by other organisms, such as the tubercle, which do not produce kinases, it seemed important to see whether plasmin preparations would liberate chondroitin sulphate from cartilage *in vitro*: such a liberation might be a step in destruction of cartilage *in vivo*.

Cartilage slices (50 mgm. wet weight) prepared from the condyles of ox femora, or from human articular cartilages, were incubated at 35° C. with phosphate–citrate buffer[9] (pH 6·2, $M/10$ with respect to phosphate) and chloromycetin (0·1 mgm./ml.) to prevent bacterial contamination, to which was added (*a*) varying amounts of a preparation of bovine plasmin (Parke Davis), (*b*) plasmin + an antiplasmin preparation. These mixtures, together with suitable controls, were incubated at 35° C. on a shaker in screw-capped bottles and at the end of varying times the fluid in the bottles was withdrawn, the cartilage slices washed with buffer and the combined washings and supernatant fluids centrifuged. The relative amount of chondroitin sulphate in the supernatant fluids was estimated approximately by two methods: (*a*) a sample of the supernatant was mixed with buffer at pH 4·2 and then acidified serum added under the conditions of Tolksdorff *et al.*[10]; the turbidity obtained was then compared with that given by known amounts of a commercial sample of chondroitin sulphate. That the turbidity obtained with the supernatant fluids was due to chondroitin sulphate was shown by incubating them with either testicular or staphylococcal hyaluronidase at pH 6·0: the former hydrolyses chondroitin sulphate, whereas the latter does not. (*b*) By hydrolysing samples of the fluids with 4 N hydrochloric acid for 4 hr. at 100°, removing the hydrochloric *in vacuo* and estimating the amount of hexosamine by the method of Elson and Morgan[11]. Table 1 shows the type of results which have been obtained with bovine cartilage. Liberation of chondroitin sulphate from bovine cartilage slices was more complete in the presence of the plasmin preparation and was stopped by so-called antiplasmin. The discrepancy between the amounts of chondroitin sulphate estimated by methods (*a*) and (*b*) presumably reflects either the lack of purity of the chondroitin sulphate standard preparation or the different degree of turbidity given by unit weights of the chondroitin sulphate liberated from the cartilage and the standard preparation. Examination of the effect of papain and trypsin on the cartilage slices showed that both of these enzymes also liberate the mucopolysaccharide. The activity of trypsin may argue against the liberation being due simply to hydrolysis of the protein associated with

Table 1. LIBERATION OF CHONDROITIN SULPHATE FROM BOVINE CARTILAGE SLICES (50 MGM. WET WEIGHT) BY BOVINE PLASMIN. The basal incubation medium consisted of 2·0 ml. of McIlvaine buffer *p*H 6·2 containing 0·2 mgm. of chloromycetin. The incubation temperature was 35°

the mucopolysaccharide complexes such as those referred to above, since Muir[4] finds that trypsin has comparatively little effect on the viscosity of solutions of her complex, prepared from pig tissue, although Mathews[2] reported that trypsin lowered the viscosity of solutions of his, prepared from ox tissue.

It thus appears possible that, if sufficient plasminogen is present in the vicinity of cartilage *in vivo*, activation by the kinase produced by staphylococcal and streptococcal infections may be sufficient to cause considerable leakage of chondroitin sulphate from the ground substances, with consequent damage to the mechanical properties of the cartilage.

Experimental Suppression of Increased Capillary Permeability in Thermal Burns in Rats

THE possibility has been widely considered that œdema in thermal injury is partly due to release of substances or activation of endogenous mechanisms which increase capillary permeability. There is little convincing evidence in support of such a hypothesis, and the œdema associated with burning has never been suppressed by pharmacological means[1].

Using a modification of the method described by Sevitt[2] to produce standard burns, we have been able to confirm his observations on the development of both an immediate and a delayed œdema by subjecting rats to a standard burn (55° C. for 27 sec.) on their abdomen.

Increased capillary permeability was estimated by leakage of protein-bound trypan blue into the superficial layers of the burnt area (estimated visually on a unitary scale from 0–10) and by measuring the water content of a standard area of skin and subcutaneous tissue in the burnt zone.

In control rats, dye-accumulation in the superficial layers began about 10–20 min. after injury and reached a maximal intensity about 60–90 min. later. The accumulation of œdema in the deeper tissues developed at a slow rate and was maximal 2–3 hr. after burning (Table 1).

In rats pretreated with mepyramine maleate ('Anthisan') (1 mgm./kgm.)[3] there was a significant delay in the accumulation of dye in the superficial layers of the burnt area (Table 1). By 60–90 min., however, no difference between the control and treated animals was discernible. There was a similar, though less striking, delay in the development of subcutaneous œdema. This was apparent only in estimations made up to 1 hr. after burning. At 3 hr. after injury there was no significant difference between the œdema of the deeper tissues of the control and treated groups.

In other rats pretreated with sodium salicylate[4] (0·66 gm./kgm. body-weight given intraperitoneally 30 min. before injury), there was a striking suppression of both dye-accumulation and œdema formation, neither of which ever reached the values found in control animals.

A third group of rats was given 3 mgm./kgm. body-weight of di-*iso*propylfluorophosphonate in arachis oil intramuscularly, 30 min. before burning. Up to 30 min. after injury there was an inhibition of dye-leakage similar to that observed in rats given mepyramine. Thereafter, however, staining of the burnt area developed more slowly than in the group treated with mepyramine and in many cases never reached the intensity observed in untreated animals. Leakage of protein-bound dye was nevertheless more extensive 3 hr. after burning in the di-*iso*propylfluorophosphonate group than in the salicylate group. However, rats treated with di-*iso*propylfluorophosphonate showed a reduction in the amount of œdema developing in the deeper tissues of the burnt area when measured 3 hr. after injury, as striking as that observed in animals treated with salicylate.

Table 1. EFFECT OF VARIOUS MEASURES ON THE ACCUMULATION OF TRYPAN BLUE AND OF ŒDEMA FLUID IN THE SKIN OF RATS SUBJECTED TO THERMAL BURNS

Treatment	No. of animals	Time after burn	Water* (gm./cm.^{2} burnt skin)	Grading of blue in arbitrary units
Controls	17	30 min.	—	4·6 ± 1·7
	20	3 hr.	0·15 ± 0·03	9·5 ± 1·03
'Anthisan'	11	30 min.	—	1·7 ± 1·28 (*P* = < 0·001)
	10	3 hr.	0·15 ± 0·059 (N.S.)	9·5 ± 1·06 (N.S.)
Salicylate	12	30 min.	—	0 (*P* = 0)
	8	3 hr.	0·05 ± 0·02 (*P* = < 0·001)	2·4 ± 0·92 *P* = < 0·001)
Di-*iso*propylfluorophosphonate	8	30 min.	—	1·6 ± 0·9 (*P* = < 0·001)
	9	3 hr.	0·07 ± 0·04 (*P* = < 0·001)	5·0 ± 1·5 (*P* = < 0·001)

* Mean water content of normal skin = 0·03 gm./cm.^{2}.
—, not tested.
N.S., not significant.

Depletion of bodily histamine and 5-hydroxytryptamine by a course of injections of compound 48/80 also delayed the onset of dye-linkage into the burnt area. BOL 148, an antagonist of 5-hydroxytryptamine, caused only a slight and inconstant delay in the onset of dye-leakage.

These results, which will be published in greater detail elsewhere, are consistent with the hypothesis that delayed increased capillary permeability seen after thermal injury is due to the consecutive operation of two or more intermediary mechanisms or chemical mediators released from the tissues. They also indicate that release of histamine may be responsible for the initial phase of such a series of events. Similar results have been obtained in inflammation due to chemical irritation[3,4]. The action of salicylate and di-*iso*propylfluorophosphonate on the later stages of the reaction to burning may be due to inhibition of the activation of globulins which increase capillary permeability. However, di-*iso*propylfluorophosphonate in particular has general effects on capillary permeability which are of interest and are the subject of further investigation.

We thank Sir Roy Cameron for his interest and encouragement and Messrs. Sandoz and Burroughs Wellcome for gifts of BOL 148 and compound 48/80 respectively.

Straight-Growth Inhibitors in Glucose

Several authors[1–5], when partitioning crude ether extracts of plant material, have saturated the aqueous phase with glucose to facilitate its separation from the ether phase.

During the course of an investigation on growth correlation inhibitors, it was found several times that extracts prepared with the addition of glucose inhibited straight growth of wheat coleoptile sections more than those without glucose. After checking other sources of inhibitory substances, it was decided to investigate the effect of glucose more fully.

Saturated solutions of glucose (usually 45 ml.) were made alkaline with an 8 per cent w/v solution of sodium bicarbonate (1–9 ml. of solution) and were shaken three times with 30 ml. of peroxide-free ether. The ether phase was discarded and the aqueous solutions acidified to *p*H 3·1 with orthophosphoric acid, and again shaken three times with 30 ml. ether. The three ether fractions were combined and reduced to 1 ml. on a water bath. Amounts equivalent to 10 gm. glucose were delivered on to Whatman No. 1 paper strips with a microsyringe[6]. Comparisons were made with extracts from 7–8 days old etiolated pea seedlings grown at 25° C. (the top inch of the stem was discarded to avoid a possible effect of indoleacetic acid on the inhibitor assay). For every 10 gm. of pea stems 1 ml. of distilled water was added to the crude ether extract, and ether evaporated and the aqueous solution filtered (Whatman No. 1). This aqueous extract was treated in the same way as the extract from the glucose solution, except that the amount of ether extract applied per chromatogram was equivalent to 20 gm. fresh weight. Chromatograms were developed in the ascending direction after an equilibration period of 6–12 hr. with the solvents given in Fig. 1. Solvents containing acetic acid were unsatisfactory, for they made the coleoptile sections flaccid and caused inhibition. This effect could not be overcome without affecting the natural inhibitors as well. Chromatograms were cut into ten equal strips, which were tested against two control strips from the same chromatogram. Nitsch's assay technique[7] was used with the minor modifications that 10-mm. sections were cut from wheat coleoptiles of the variety Cross 7.

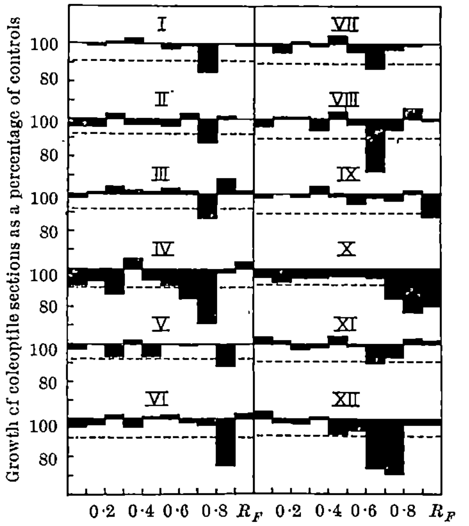

Fig. 1. The response of wheat coleoptiles to 10 gm. of different samples of glucose (I, A.R. grade; II and III, samples obtained from H. F. Stevens, Christchurch, in 1953 and 1958 respectively), and 20 gm. of stems of etiolated pea seedlings (IV); solvent, butanol/25 per cent ammonia/water (100 : 8 : 100). V–XII, glucose and peas using different solvents: V (glucose) and VI (peas), 96 per cent ethanol/25 per cent ammonia (9 : 1); VII (glucose) and VIII (peas), *iso*propanol/25 per cent ammonia/water (8 : 1 : 1); IX (glucose) and X (peas), 70 per cent ethanol; XI (glucose and XII (peas), distilled water. Growth has been plotted as a percentage of the growth of control sections; the broken line represents the level at which differences are significant ($P = 0·05$). The mean growth of control sections in different experiments was 7·88–8·84 mm. over a period of 17–18 hr.

Results are illustrated in Fig. 1. They show that all three samples of glucose of different origin (one of which was A.R. grade) contained a straight-growth inhibitor the position of which on the chromatograms was identical with that of 'inhibitor β' which occurs in etiolated pea seedlings (I–IV). The same held true for four other solvent systems (V–XII).

In another experiment the inhibitors from 250 gm. of glucose and from 250 gm. of peas were eluted from several chromatograms, and the concentrated eluates were applied to paper strips in a wide range of con-

Table 1. The Effect of the Inhibitors in Peas and in Glucose eluted from Chromatograms, at Various Concentrations

Concentration*	Growth of coleoptile sections as a percentage of controls†	
	Pea stems	Glucose
100 *G*	54·7	72·3
10 *G*	83·2	90·0
1 *G*	88·7	91·8
0·1 *G*	101·3	91·8
0·01 *G*	94·3	97·9

* *G* is equivalent to 1 gm. fresh weight of pea stem tissue or 1 gm. of glucose respectively.

† Significant differences ($P = 0·05$) from controls 10·8 and 9·5 per cent respectively.

centrations. Again, the results (Table 1) show a similar pattern for both inhibitors, although on a dry weight basis the amount of inhibition was much less in glucose than in peas.

Varga and Ferenczy[8] detected 'inhibitor β' in fruits of thirty different species belonging to ten families and the many references listed by Ferenczy[9] illustrate its widespread occurrence. This report, the fact that glucose is prepared from plant sources, and the identical position on chromatograms prepared with five different solvents suggest a possible similarity between the inhibitor found in peas, and glucose. Apart from this suggestion, this communication is intended as a warning against the use of inadequately purified glucose when partitioning extracts which are to be assayed for growth substances by the coleoptile straight growth test.

Use of Lyophilized Formol-treated Red Cells in Blood-Group Serology

Moskowitz and Carb[1] have reported that treatment of human red cells with formalin inhibits their agglutinability without impairing their absorptive power for the corresponding blood-group agglutinin. During the course of a similar investigation, we have confirmed these findings and also the observation of Weinbach[2] that formol-treated red cells are sufficiently 'toughened' to withstand freeze-drying by lyophilization. We have found that such lyophilized cells re-suspended in normal saline retain their original absorptive capacity for blood-group agglutinins, and that eluates prepared from these cells by Landsteiner's heat method, following absorption, are as active as those from untreated cells. No hæmolysis has occurred during elution.

So far as we are aware, lyophilized formol-treated red cells have not previously been put to practical use in blood-group serology, and we wish therefore to direct attention to a practical application of this technique. We encountered recently a sample of red cells which reacted similarly to certain rare cells described by Weiner *et al.*[3] and given the symbol A_m, which showed a marked hæmolysis when we attempted to store them at low temperature in glycerol. These red cells were not agglutinated by group O immune type anti-A sera but readily absorbed anti-A. Exposure to formol-saline and lyophilization enabled these cells to be preserved satisfactorily without impairing their power of absorption and subsequent elution.

The technique we have used in the initial treatment with formalin differs in some respects from that of Moskowitz and Carb and is as follows. One volume of formaldehyde solution (analytical reagent, approximately 36 per cent w/v HCHO) diluted 1 in 30 with non-buffered normal saline is incubated at 37° C. with an equal volume of washed packed red cells. After 12–24 hr. incubation the treated red cells are washed three times in normal saline and then dried from the frozen state. If immediate lyophilization is not convenient, the formol-treated cells may be stored under distilled water at 4–6° C. Storage under distilled water has proved more satisfactory than under normal saline since, while some degree of hæmolysis tends to occur with the latter, formol-treated red cells stored for up to one week under distilled water have shown no trace of hæmolysis.

Relationship between Certain Biological Constants and Trophic Condition in Mosquito Populations

Macdonald[1] has shown that the composition of mosquito populations, as regards the proportion in the parous state, can be calculated theoretically, yielding an equation which involves the daily survival-rate and a time period based on the gonotrophic cycle. This, and a modified equation given by Davidson[2], have provided a useful means for calculating daily survival rates in the field. Using similar methods, it is possible to derive a general expression which determines the composition of populations as regards the proportion in the unfed condition.

Assuming a population in a steady equilibrium, with a daily hatch of M mosquitoes, and a daily survival-rate of p, then the number aged x days will be Mp^x. Then let: n = days from hatch to first feed; d = days developing eggs, up to the first oviposition; f = days from oviposition to next feed; $c = d + f$.

This cycle will be repeated every c days. Then, numbering the days after emergence 0, 1, 2, . . . etc., the days on which mosquitoes are in a given state are as shown below:

Unfed	
$0, 1, 2$	$n - 1$
$n + d, n + d + 1, n + d + 2$	$n + c - 1$
$n + c + d, n + c + d + 1, n + c + d + 2$	$n + 2c - 1$
Fed and/or developing eggs	
$n, n + 1, n + 2$	$n + d - 1$
$n + c, n + c + 1, n + c + 2$	$n + c + d - 1$
$n + 2c, n + 2c + 1, n + 2c + 2$	$n + 2c + d - 1$
etc.	

Let G = number which are fed and/or developing eggs;

$$\text{then } G = M(p^n + p^{n+c} + p^{n+2c} \ldots + p^{n+1} + p^{n+c+1} + p^{n+2c+1} \ldots + p^{n+d-1} + p^{n+c+d-1} + p^{n+2c+d-1} \ldots)$$

$$= M\left(\frac{p^n}{1-p^c} + \frac{p^{n+1}}{1-p^c} + \frac{p^{n+2}}{1-p^c} \ldots + \frac{p^{n+d-1}}{1-p^c}\right)$$

$$= \frac{M}{1-p^c}\left[(p^n + p^{n+1} + p^{n+2} \ldots + p^{\infty}) - (p^{n+d} + p^{n+d+1} + p^{n+d+2} \ldots + p^{\infty})\right]$$

$$= \frac{M}{1-p^c}\left(\frac{p^n}{1-p} - \frac{p^{n+d}}{1-p}\right)$$

$$= \frac{M(p^n - p^{n+d})}{(1-p)\ (1-p^c)}$$

Let P = total population of mosquitoes ;

then $P = M(1 + p + p^2 + p^3 \ldots p^\infty)$

$$= \frac{M}{1-p}$$

Therefore, if g = proportion of the population which is fed and/or developing eggs ;

$$\text{then } g = \frac{G}{P} = \frac{p^n - p^{n+d}}{1-p^c}$$

and, if u = proportion in the unfed state,

$$u = 1 - \frac{p^n(1-p^d)}{1-p^c}$$

Two special cases may be noted, which yield simplified equations :

(*a*) where $n = f$; then $u = \dfrac{1-p^f}{1-p^c}$;

(*b*) where $f = 0$; that is, where oviposition and refeeding occur on the same night ;

$$\text{then } u = 1 - p^n$$

Thus, if the proportions u or g are known from representative samples of mosquitoes from natural resting places, a knowledge of any three of the quantities p, n, d and c allows calculation of the fourth. In practice, this will usually mean calculation of survival rate from details of the gonotrophic cycle. The method has been tested with four Malayan species of *Culex*, the survival rates of which have been estimated by other means, and close agreement has been found ; these results will be published elsewhere. This suggests that, in certain species at least, the above relationship may provide a useful means for following alterations in survival rate, for example, during control campaigns, although where anomalous gonotrophic cycles occur, for example, with a pregravid phase, the equations will require modification.

Effect of Nitric Oxide on the Radiosensitivity of Tumour Cells

FOLLOWING the important observation of Howard-Flanders[1] that the presence of a low concentration of nitric oxide in the medium in which bacteria are suspended at the time of irradiation confers a level of radiosensitivity comparable with that of an equal concentration of dissolved oxygen, we have investigated the effects of nitric oxide on the radiosensitivity of tumour cells.

As judged by the time of appearance of tumours which arise from a standard inoculum of irradiated cells, we find that nitric oxide is capable of raising the level of radiosensitivity of anoxic tumour cells to that which they would have if irradiated in the presence of dissolved oxygen.

The Ehrlich ascites tumour cells used for irradiation were harvested from white mice (Fox) which had been inoculated five days previously with $\sim 2 \times 10^7$ cells. Since nitric oxide readily combines with hæmoglobin, erythrocytes were removed as completely as possible by two osmotic shock treatments in distilled water, terminated after 40 sec. by addition of double-strength saline. In this, and in most other respects, our technique followed closely that which had been elaborated by Scott for the study of factors which may influence the radiosensitivity of tumour cells[1]. Cells were finally suspended in saline for irradiation at 5×10^7 cells/ml. The nitric oxide was prepared by adding glacial acetic acid to a warm concentrated solution containing sodium nitrite and ferrous sulphate. After washing the gas to remove traces of nitrogen dioxide, oxygen was excluded as rigorously as possible at all stages. All cell suspensions were rendered strictly anaerobic by gas exchange with an atmosphere of oxygen-free nitrogen (British Oxygen Co.) and by their own respiration in this atmosphere before they were irradiated or treated with nitric oxide. A 4-ml. sample of the cell suspension containing 2×10^8 cells was exposed to 1,200 r. of 200 kV. X-rays filtered through 0·5 mm. copper and 1 mm. aluminium at 325 r./min. in a 'Perspex' vessel through which gas could flow (Deschner, E. E., and Gray, L. H., in preparation). In two experiments the nitric oxide was added to the saline cell suspension in the form of a solution in $1 \cdot 5\ 10^{-3}$ *M* ferrous sulphate, and a slow stream of nitrogen passed through the vessel during irradiation as a safeguard against the entry of oxygen. At the end of each irradiation or control treatment the nitric oxide was displaced by a vigorous stream of nitrogen before the cells were exposed to air. Finally, 0·2 ml. inocula from the treated fluid were introduced into each of six mice. In these experiments a control was run which showed that the effect of the mixture in raising the sensitivity of the cells was attributable mainly to the nitric oxide and not to the ferrous sulphate. In the remaining experiments the ferrous sulphate was dispensed with. Cell suspensions were brought into equilibrium with a gas phase which contained 100, 20, 10 or 2 per cent nitric oxide/nitrogen mixtures, and the same gas was passed over the cells during irradiation.

In most experiments the cells were in the presence of nitric oxide for a maximum of 15 min. Fig. 1 shows that tumours appear in animals inoculated with cells which had been treated with nitric oxide as soon as in animals which received control inocula. Contrasting this with the larger difference in the time of appearance of tumours which arose from cells irradiated in nitrogen and in oxygen, it is evident that any toxicity the nitric oxide may have had was quite insignificant as regards ultimate cell survival. Likewise, exposure of cells to 1,200 r. under completely anoxic conditions, and in the absence of nitric oxide, only slightly delayed the appearance of tumours. When, however, the cells were irradiated in the presence of nitric oxide the appearance of tumours was much delayed. In some cases, no tumours appeared at all within the 30-day observation period, and in every one of 18 irradiations in which nitric oxide was added before irradiation at an initial concentration greater than 10 μM the appearance of the tumours was delayed compared with that of tumours which grew from cells which had been treated with nitric oxide only or exposed anaerobically to X-rays. This evidence, however, is not in itself sufficient to establish the radiosensitizing action of the nitric oxide, since it is possible, in principle, that there may be synergism between the two separate

* Total nitric oxide present in solution or complexed with ferrous sulphate.

injuries, namely, that due to the radiation and that due to the chemical toxicity of the nitric oxide, which could be mistaken for radiosensitization. To decide critically between these two alternatives, we concentrated most of our effort on pairs of treatments, in one of which nitric oxide was present before and during irradiation and the 'control' in which the cells were irradiated anoxically but exposed to the same nitric oxide concentration for an equal total time shortly after irradiation. Fig. 1 presents results obtained in one group of experiments in which nitric oxide was used as 20 and 10 per cent nitric oxide/nitrogen mixtures. For comparison, one group is included from another experiment to show the effect of 1,200 r. on the growth of cells irradiated aerobically.

It is quite evident that in all ten groups of animals tested in pairs, nitric oxide given before and during irradiation (broken lines) is more effective than when given after irradiation (full lines). In 4 out of 5 critical pairs, the growth of tumour cells irradiated in the presence of nitric oxide corresponded to a degree of damage as great as that which would have been sustained by cells which were aerobic at the time of irradiation. All the results obtained so far in one pilot and four principal experiments are recorded in Table 1. The figures indicate the status of mice, whether with or without tumours, on the tenth day after inoculation of 10^7 treated cells. We believe that these observations establish that nitric oxide is comparable in effectiveness with oxygen in raising the radiosensitivity of tumour cells with respect to the loss of reproductive integrity of those cells on exposure to X-radiation.

Kihlman[3] has recently reported that nitric oxide has a similar action with respect to the induction of chromosome structural damage in *Vicia* root meristem cells.

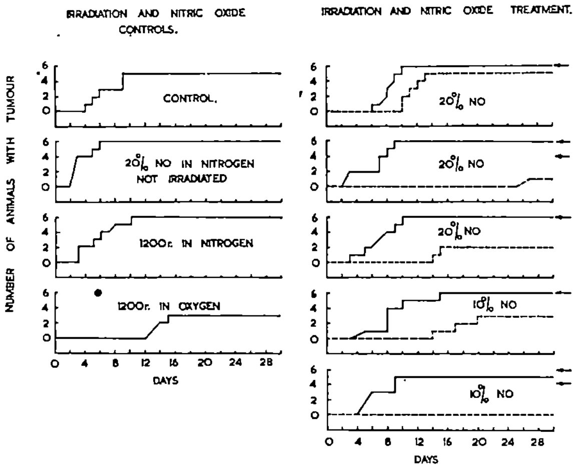

Fig. 1

The fact that there are now three known types of cell, namely, bacteria, plant meristem and mammalian tumour cells in which the molecule of nitric oxide can apparently take the place of oxygen in enhancing sensitivity to X-rays opens new means of exploring the role of oxygen itself.

We are grateful to Dr. O. C. A. Scott, who was prevented by illness from participating in these experiments, for guidance in the procedure for assaying cell survival, and to Dr. D. L. Dewey for assistance in one experiment. One of us (F. O. G.) wishes to acknowledge financial aid during the time of the investigation in the form of fellowship grants from the following groups or sources: the Jane Coffin Childs Memorial Fund for Medical Research; the Osborne Memorial Fund; the Alumni Faculty Research Fund; and the Chemistry Department of Wheaton College.

Effect of Maize on Fat Hardness and Growth-Rate in Bacon Pigs

EIGHTEEN Large White pigs (13 females and 5 males) were fed from 100 lb. to slaughter-weight (200 lb.) on rations containing 15, 30, 45, 60, 75 and 90 per cent maize, the rest of the rations consisting of pollards, barley meal, carcass meal and minerals. The crude protein content of the rations varied from 14 to 16 per cent and the three pigs in each group were chosen at random. Feed consumption and live-weight increase were measured, and samples of fat from shoulder, back and loin were taken 24 hr. after slaughter for analysis by the Hanus method for iodine value.

The iodine values of the fats from male pigs were corrected by adding 1·7, as suggested by Lush *et al.*[1], to make them comparable with those from females. They showed wide variation within groups, and the three regression equations for per cent maize on iodine values of shoulder, back and loin fats were significant only at the 20/1 level, with low accountable variance. Nevertheless there was a definite trend in all three sets for fat hardness to decrease as the

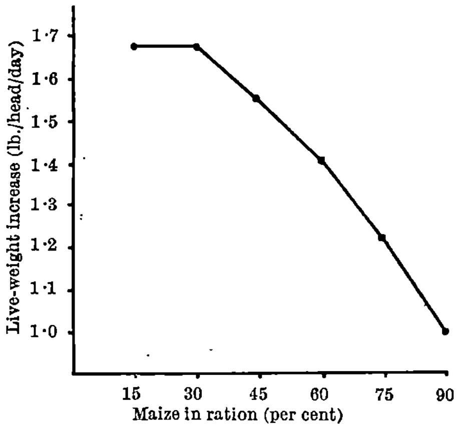

Fig. 1. Effect of maize on growth-rate from 100 lb. to 200 lb. live-weight

percentage of maize in the ration increased, although all the fats were sufficiently hard for curing into bacon and ham. In the factory the fats of 15 pigs were classed as 'very firm', and those of three 'firm', the latter being pigs on 15, 45 and 60 per cent maize.

The percentage of maize in the ration had no significant effect on the feed conversion ratio. There was a wide individual range, from 3·0 to 5·0, while group averages varied irregularly between 3·7 and 4·2. The most efficient individual conversion ratio (3·0) was obtained from a pig on 90 per cent maize, while the least efficient (5·0) was from a pig on 45 per cent maize.

There was a very striking relation between the percentage of maize in the ration and the rate of live-weight increase, and the group averages are plotted in Fig. 1, which shows a regular decrease in daily live-weight gain with increasing proportions of maize above 30 per cent. The regression equation for this relation was significant to more than 1,000/1, with 61 per cent accountable variation. This effect of maize in reducing the rate of growth probably accounts for the tendency for the fat to be softer in pigs on the high-maize rations, since Callow *et al.*[2] found that fast-growing pigs tend to have fat with a low iodine value and slowly growing pigs to have fat with a high iodine value.

The high-maize rations did not appear to lack palatability, and thus the regular decrease in the rate of live-weight gain with increasing percentage of maize in the ration suggests a nutritional deficiency in maize. Krehl *et al.*[3] concluded that zein has an unbalanced amino-acid composition which results in greatly reduced synthesis of nicotinic acid in the body and a higher requirement of tryptophan or nicotinic acid. The tryptophan contents of these rations, calculated from data by Harvey[4] and Fowden and Wolfe[5], were approximately the same, but the proportion of the total tryptophan which was derived from maize increased from 11 to 87 per cent. Nicotinic acid-deficiency in maize was reported by Braude *et al.*[6], who found that young pigs on a diet deficient in nicotinic acid and containing 79 per cent maize failed to gain weight, while another group on the same ration supplemented with 6 mgm. nicotinic acid per head per day gained an average of 5 lb. per week. They concluded that almost all the nicotinic acid in maize is in an alkali-labile 'bound' form which is not available to the pig.

From these results we suggest that the tendency for maize to produce soft fat in bacon pigs may be due to slow growth caused by a higher requirement of tryptophan or a deficiency of 'free' nicotinic acid, and that high-maize rations for pigs may require supplementary nicotinic acid. Other amino-acids may also be involved, and experiments to test these points are now in progress.

Temperature and Germination in *Kennedya* Vent.

During the course of studies in the genus *Kennedya*[1] it was considered desirable to determine the germination response of a range of species and ecotypes to different constant-temperature levels. Germinations were made in sand maintained at 60 per cent of the water-holding capacity. A seed was recorded as germinated when the radicle had attained a length of 5 mm. The temperatures used and some typical results are shown in Table 1.

Table 1. Total Germination Percentages after 33 days at Four Temperature Levels

Species	Line No.	10° C.	15° C.	20° C.	25° C.
1 *K. coccinea* Vent.	*G*4	93·3	94·2	80·8	46·7
2 *K. eximia* Lindl.	*E*12	61·7	72·5	55·8	25·0
3 *K. carinata* Benth. (Domin.)	*X–P*6	90·0	95·8	13·3	3·3
4 *K. prostrata* R.Br.	*A*79	78·3	89·2	5·0	0·8

Optimum temperature (that giving highest percentage at fastest rate) was generally found to be between 15° C. and 20° C. with a sharp decline at 25° C. *Kennedya carinata X–P*6 and *Kennedya prostrata A*79, however, showed spectacular decreases in germination percentage from 15° C. to 20° C. Such a dramatic effect of temperature at these moderate levels is uncommon.

Results were repeatable, and it was therefore decided to compare germination behaviour of *K. carinata* under simple alternation between 'favourable' and 'unfavourable' temperatures. Treatments were: (1) five days at 15° C., then constant 20° C. (2) five days at 20° C., then constant 15° C. (3) constant 15° C. The resultant cumulative germination percentages are shown in Fig. 1. At 21 days after commencement, treatment (1) was returned to 15° C.

It was expected that pre-treatment at 20° C. would accelerate germination at 15° C. due to more rapid imbibition at the higher temperature. However, comparing treatment (2) with (3) (control) we find that curves are essentially similar but that the former has been displaced in time. Thus rather than accelerate germination, pre-treatment at 20° C. has had a retarding effect. Treatment (1) shows that

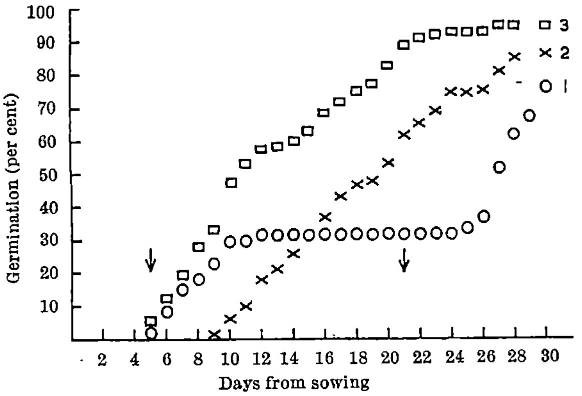

Fig. 1. Cumulative germination percentages of *K. carinata* for (1) 15–20–15° C. (circles), (2) 20–15° C. (crosses), (3) constant 15° C. (squares). Arrows indicate time of transfer

the inhibiting effect of 20° C. is not immediate in action since transfer of seeds from 15° C. to 20° C. did not at once preclude germination: there was a delay of five days before the curve levelled off. This behaviour suggests that 20° C. does not influence all phases of radicle growth but only its commencement. Once initiated in a proportion of the imbibed seeds at the lower temperature, growth continues and results in germination at the higher temperature. No further germination occurs until five days after re-transfer to favourable temperature, thus indicating that the time interval between initiation of radicle growth and completion of germination at 15° C. is approximately five days.

Artificial Mutagenesis in Plant Breeding

MANY difficulties and disadvantages are involved in undertaking a programme of improvement of crop plants by the artificial induction of mutations. Among those which have been recognized are (*a*) the necessity for screening very large populations of plants; (*b*) the considerable degree of sterility found in mutant material; (*c*) the inefficiency of existing mutagens, and (*d*) in inbreeding forms, the desirability of isolating the frequently male-sterile R_1 generation, to avoid contamination with foreign pollen. The first of these difficulties is less troublesome in certain instances, as for example, when screening seedlings for disease resistance, for large numbers are easily handled. No doubt, for this reason, many reports[1] of the successful induction and selection of disease resistant mutants do in fact exist; resistance to *Erysiphe graminis f. hordeii* in barley, to *Puccinia glumarum* and *Puccinia graminis f. tritici* in wheat, and to *Puccinia graminis f. avenae* in oats, are among the most important.

We have recently attempted to induce in *Hordeum sativum* (variety Proctor) mutants resistant to *Erysiphe graminis f. hordeii*, and our results have indicated a still further source of uncertainty in mutation breeding.

Dormant seeds (water content 10·6 per cent) were exposed to either 10,000 rads of γ-rays from a cobalt-60 source, or to 2·2 × 10¹² thermal neutrons per cm.², and sown immediately afterwards in field plots. No other variety of barley was grown within a distance of at least one mile in any direction from the plots. R_2 seeds were sown in September, and the seedlings kept under polyethylene cages in a greenhouse. A fortnight after sowing, when the seedlings were at the two-leaf stage, a mixture of conidia, previously collected by suction pump from control plants and stored in talc at 3° C., was blown over the seedlings. Under these conditions there was 100 per cent infection of control plants (reaction type 4, scale 0–4, 4 being completely susceptible) but little sign of infection of a control resistant variety. No attempt was made to isolate the different races of the pathogen, but tests with the differential varieties of Newton and Cherewick indicated that the predominant one present was race 6. 18,490 R_2 seedlings were tested, and the frequency of chlorophyll mutations within them was as follows:

	R_2 plants	Chlorophyll mutants
γ-ray treatment	13,140	104
Thermal neutron treatment	5,350	37

No viable R_2 plant was found showing any degree of resistance to *Erysiphe graminis f. hordeii*.

These results differ strikingly from those of other workers. Hansel and Zakovsky[2], for example, found a similar number of chlorophyll mutations, as well as 190 greenhouse- and 72 field-resistant lines in 15,000 R_3 lines (R_2 ear progenies) of Volkorn barley treated with 9,400 r. X-rays. They attributed this very high rate of induction of resistant mutants to the presence of a large number of loci for this character rather than to a high mutation rate. Knowing the mutation-rate here, then from the mutation-rate of other genes in plants it might be possible to estimate the number of loci involved. If we take only the field-resistant mutants in Hansel and Zakovsky's data, they quote that the values represent two resistant mutants in every 1,000 R_2 seed. Most of the X_3 lines bred true for resistance. 15,000 R_2 ear progenies might represent 5,000 R_2 seed; 10 of these, therefore, will be mutants. Assuming 20 seeds per ear, as they do, and a 3 : 1 segregation of a gene for resistance, the ten R_2 mutant seed would be produced in at least two ears. Therefore, two R_1 ears in 250 had mutant seed (the ear initial is the unit of mutation in a seed). This value assumes no differential intrasomatic elimination of cells containing the mutant gene, and ignores the considerable number of greenhouse-resistant lines. Mutation-rates are known for very few genes in plants. Lewis[3] quotes rates from 0·008 to 0·01 per r. per 10⁶ genes for *S* alleles in *Oenothera*, after treatment of pollen mother cells with X-rays, and mutation-rates of the same order have been reported in animals and lower organisms. Though no strictly relevant figures exist, the data do allow us to draw the conclusion that in Volkorn barley there are probably many hundred loci involved in the determination of mildew resistance.

These contradictory results from two separate attempts to induce mildew resistance in barley emphasize yet another difficulty facing a plant breeder attempting to justify a programme of mutation breeding. A thorough knowledge of the genotype being dealt with, in terms of (*a*) the condition of the gene or genes controlling the character sought, that is, whether dominant or recessive, and (*b*) the number of loci involved, now appears to be of basic importance in making this decision. The fact that similar genes controlling like processes have different mutation-rates[3] is yet another complicating factor. In the absence of such information, and with our present lack of understanding of the process of mutagenesis, and of the factors affecting it, a programme of mutation breeding becomes an extremely speculative affair. The potential value of artificial mutagenesis as a technique remains, however, but a great amount of fundamental work has to be undertaken before its potentiality can be fully exploited.

We are indebted to Prof. K. Mather for guidance in the preparation of this report.

Microbial Antagonism of *Fusarium culmorum*

DURING a survey of soil- and root-invading fungi in swards of perennial rye-grass carried out in 1956 and 1957 particular attention was given to the occurrence of *Fusarium culmorum* (W.G.Sm.) Sacc. This species, which is considered to be a soil inhabitant, is also a weak parasite of the roots of many members of the Gramineae, and during the survey it was isolated regularly from soil and from the roots of rye-grass. We find that its occurrence in both of these substrates is influenced by microbial antagonisms.

In soil, the occurrence of *F. culmorum* showed marked seasonal variations which could not be related to either soil temperature or moisture considered separately. There was, however, indication of an interaction between these factors. With high soil moisture the abundance of *F. culmorum* was positively correlated with rising temperature. At low moistures, on the other hand, there appeared to be strong inhibition above 8–9° C. These observations were substantially confirmed in an experiment in which unsterilized soil, taken from the rye-grass swards, was incubated under a range of moisture and temperature conditions. Again it was found that under low-moisture conditions there was marked reduction in the recovery of *F. culmorum* at temperatures above 10° C.

This effect of temperature is not a direct one, for the fungus grows well at high temperatures in soil with a low-moisture content. Its interaction with *Trichoderma viride*, which was abundant in the soil investigated, was, under low-moisture conditions, very striking and appears to account for the observed results. When *F. culmorum* and *T. viride* were grown together in soil at a moisture content of 40 per cent m.h.c., *F. culmorum* was dominant up to temperatures of 10° C. Above this temperature, however, it was completely suppressed by *T. viride*.

In a study of the pathogenicity of *F. culmorum* towards rye-grass a bacterium was found to be regularly present on the root surfaces, particularly of healthy roots. It was noted that this bacterium was antagonistic to *F. culmorum* on agar plates, and this aspect was investigated further. Surface sterilized seeds of rye-grass were sown in sterilized soil which had been inoculated with *F. culmorum* alone, *F. culmorum* + bacteria, and bacteria alone. It was found that under these conditions *F. culmorum* alone produced root browning accompanied by withering of the leaves, whereas in the presence of the bacterium the symptoms were substantially reduced. No pathological symptoms were observed in the seedlings raised in soil inoculated with the bacteria alone.

There can be little doubt that the bacterium is restricted to the rhizosphere. Although it was abundant on root surfaces it was only occasionally isolated from soil where its sporadic occurrence might well be expected since small root fragments would inevitably be present. The existence, in the rhizosphere, of organisms antagonistic to root pathogens has long been suspected and was apparently first suggested by Hiltner[1]; but there has been little experimental evidence to support this view. Hitherto the only cases of protective effects by rhizosphere populations have been attributed to the antagonistic effects of *T. viride*, which is preferentially favoured by the rhizosphere environment of certain plants[2].

The nature of the bacterium has been investigated and has been shown to be a polarly flagellated organism with the typical morphology and flagellation of a *Pseudomonas* and the biochemical reactions of a *Klebsiella aerogenes*[3].

Induced Swarming of a Nematode as a Means of Isolation

SINCE nematodes extracted from soil usually comprise a mixture of species, the isolation of a pure species population for experimental purposes is frequently a laborious procedure involving the picking of individual specimens from a suspension. The tendency of *Tylenchorhynchus martini* Fielding 1956 (Nematoda, Phasmidia) in aqueous suspensions to swarm (congregate in masses) has been used to obtain large numbers of this nematode relatively free of other species. In a series of tests, mixed populations of *T. martini* and other nematodes were extracted from soil around rice plants and incubated overnight in aqueous suspensions in Petri plates. The resultant masses of *T. martini* were observed under a dissecting microscope, carefully removed with a suction pipette and transferred to a small quantity of water in an Ehrlenmeyer flask. The nematodes were dispersed by shaking and then transferred to water in Petri plates for re-incubation. This procedure has been repeated several times with no apparent loss in swarming intensity, although about 5 per cent of the population of *T. martini* in each test does not swarm and is lost in subsequent transfers. Suspensions of 50–100 thousand nematodes of 70–80 per cent *T. martini* have been purified in two serial swarmings to more than 99 per cent *T. martini*, with a virtual elimination of organic and mineral debris. Factors which stimulate swarming include a high proportion of active *T. martini* in the mixed population and a suspension density such that the individual nematodes of this species are in contact in a shallow aqueous layer. A range of room temperatures and of water reactions varying from *p*H 3·5 to 7·5 have not influenced swarming intensity.

Cardiac Glycosides and Thyroidal Iodide Transport

DURING the past few years, it has become apparent that an important action of the cardiac glycosides involves the transport of potassium ions into the cell. It has also become possible, by the use of potassium-depleted erythrocytes, to test the relative inhibitory potency of such glycosides or their aglycones *in vitro*[1,2]. Approximately 80 per cent of the potassium influx can be inhibited by the glycoside by an action that appears to involve competition by drug and potassium ions for the active transport site. The transport of chloride ions in the stomach appears to be similarly affected[3]. Since the maintenance of a concentration gradient for iodide by an 'active transport' is one of the fundamental properties of thyroid tissue, we determined whether or not iodide transport was likewise inhibited by the cardiac glycosides.

Sheep thyroid slices (~150 mgm.) were incubated for 70–90 minutes at 37° C. in Krebs–Ringer phosphate medium (3 ml.), *p*H 7·4, containing 10^{-3} *M* 1-methyl-2-mercaptoimidazole, to block organic iodine formation, and 0·2–0·3 μc. of carrier-free iodine-131. The iodine-127 content varied from 0·15 to 0·20 μgm. per 100 ml. Cardiac glycosides were dissolved in absolute ethanol, diluted with water and added to the flasks as 0·1 of the final volume to yield a final ethanol concentration of 1–2 per cent. Controls received equivalent quantities of ethanol. Results are expressed as the ratio of iodine-131 content per gram of tissue to the iodine-131 content per ml. of medium (*T*/*M* ratio).

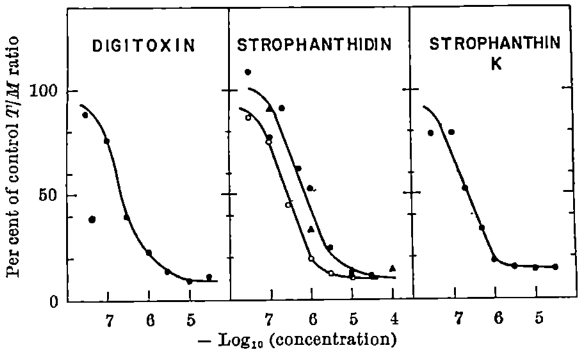

Fig. 1. Effect of cardiac glycosides on the thyroid/medium ratio (*T*/*M* ratio) of iodine-131 in sheep thyroid slices. The control *T*/*M* ratios varied from 12–25 : ● and ▲, experiments 1 and 2, fitting approximately the same curve; ○, experiment 3

Table 1. INHIBITION OF IODIDE TRANSPORT BY CARDIAC GLYCOSIDES

	Concentration for 50 per cent inhibition of the *T*/*M* ratio* (*M*)	
	Sheep thyroid slices	Rat tumour slices
Digitoxin	2×10^{-7}	$1·5 \times 10^{-4}$
Strophanthidin	$2–5 \times 10^{-7}$	9×10^{-4}
Strophanthin *K*	2×10^{-7}	

* Incubated at 37° C. under air in Krebs–Ringer phosphate buffer, *p*H 7·4, for 70–90 min.

The results, depicted in Fig. 1, demonstrate that two glycosides, digitoxin and strophanthin *K*, as well as the aglycone strophanthidin, all depress the *T*/*M* at concentrations comparable to those found to inhibit potassium transport. For strophanthidin, the results of three separate runs show the variation in responsiveness that occurs between different batches of glands. The inhibitory potency of the drugs can be compared at the point of 50 per cent inhibition (Table 1). The order compares more closely with that of Solomon *et al.*[2] than that of Kahn and Acheson[1]. The concentrations for 50 per cent inhibition are probably somewhat lower, since the curves do not go below 10 per cent of the control *T*/*M* value (Fig. 1).

We have recently described a thyroid tumour in rats in which the iodide-concentrating mechanism survived without the further steps in hormone synthesis[4]. As shown in Table 1, the iodide concentrating mechanism of these tumours is about 1,000-fold less sensitive to the cardiac glycosides than is normal sheep thyroid tissue. Another tissue that normally maintains an iodide gradient is the submaxillary gland of mice[5]. Preliminary experiments with submaxillary glands of *C3H* mice have yielded variable results : no inhibition at 10^{-4} *M* strophanthidin and 30 per cent inhibition with 10^{-4} *M* digitoxin. We were, however, not able to obtain mice with salivary *T*/*M* ratios as high as those previously reported.

The above results indicate that thyroid tissue transports iodide by a system that is sensitive to inhibition by the cardiac glycosides. The kinetics of the inhibition and the relation of iodide to potassium transport are now under investigation.

We should like to thank Dr. J. E. Rall for his advice during the course of this work, and I. L. Cooperstein for permitting us to see the manuscript of ref. 3 prior to publication.

Spontaneous Electrical Activity in the Denervated Muscles of the Cockroach *Periplaneta americana*

SPECIAL features of the anatomy and physiology of the invertebrate neuromuscular junction raise the question of to what extent the changes caused by denervation of the insect muscles are analogous to those in the denervated muscles of vertebrates.

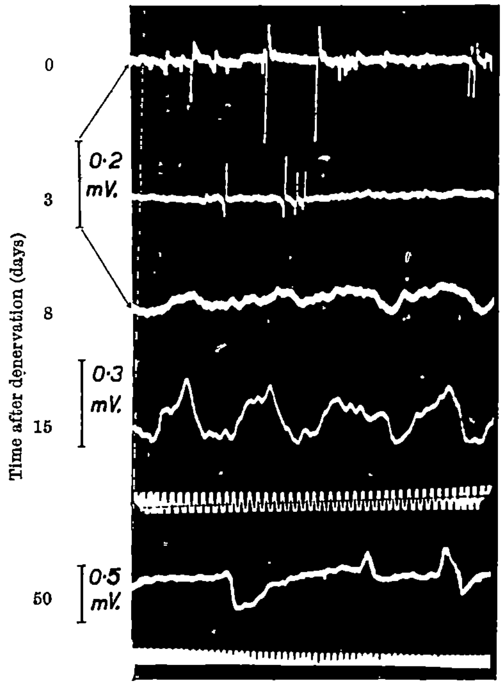

Fig. 1. Development of spontaneous electrical activity in the femoral muscles of the cockroach after denervation. Time scale: 500/sec.

Experiments were carried out to ascertain whether denervation of insect muscle is followed by spontaneous activity comparable with the well-known fibrillations in the denervated striated muscles of vertebrates. Voskresenskaya[1] described rhythmical spontaneous twitches in the extremity of the locust as early as the first day after denervation. Recently, Case[2], in visual observations of the denervated muscles of the abdominal spiracles of the cockroach, found "nearly continuous slow contractions and relaxations of small groups of muscle fibres" and called this phenomenon fasciculation. In the present experiments, the electrical activity of the denervated insect muscle was studied.

Adult males of *Periplaneta americana* (L.) were used. One extremity was denervated by cutting the nerves between the metathoracic ganglion and the left leg. Action potentials were recorded for the coxal and femoral muscles 0, 3, 8, 15 and 50 days after denervation. Monopolar insulated steel electrodes with a tip of approximately 35μ inserted through the chitin were used throughout the experiments. To prevent artefacts due to possible movements of the intact parts of the animal, the recording was performed on a metathoracic preparation obtained by isolating the metathorax with the extremities from the abdomen and the rest of the thorax. The open tracheæ ensured good metabolic conditions in this preparation.

Immediately after denervation, spontaneous electrical activity appeared as frequent pulses of short duration. Their duration (0·6–0·8 msec.) suggests their nervous origin. They were less frequent on the third day after denervation and from the eighth day they were replaced by a new type of activity, which was characterized by waves of 6–14 msec. duration with superimposed deflexions of 3–5 msec. The large waves became more numerous and increased in amplitude with time after denervation. The activity was irregular, of varying amplitude and disappeared and reappeared gradually at irregular intervals of 0·5–3 min. (50 days after denervation distinct long-duration spikes could be distinguished in the record, but at this time interference due to re-innervation cannot be excluded[3].)

It is presumed that the observed potential changes are an expression of spontaneous activity in the denervated muscle fibres with a varying degree of synchronization. They differ from the electrical activity of denervated vertebrate muscles, as was shown by a recording from the denervated tibial muscle of the rat using the same electrode, where only the usual short-duration spikes of individual fibres could be detected. When evaluating the denervation activity in the cockroach, it must be remembered that this can be the result of simultaneous potential changes in the various elements (slowly and fast contracting fibres) of the insect muscle.

Influence of Trace Elements upon Plant Protein Composition

Mulder's work[1] has shown that whereas macro-elements did not alter the amino-acid composition of potato protein, they did significantly alter the amino-acid composition of its soluble non-protein nitrogenous fraction. The influence of micro-nutrients on the amino-acid composition of plant proteins has not been properly studied, although there is evidence which suggests it might be appreciable[2]. There is, in fact, reason for believing that micro-elements may alter the relative proportions of the amino-acids in

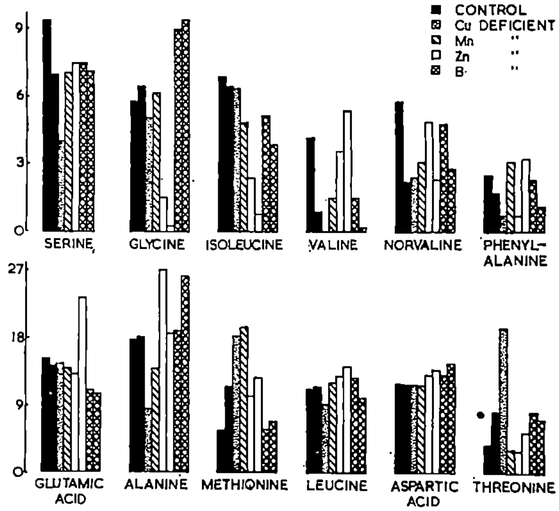

Fig. 1. Amino-acids of digests of plants deficient in trace elements as percentages of total amino-acids present. There is no detectable valine in the copper-deficient plant. One of the serine samples in the zinc-deficient plants was lost. Only single estimations of copper- and manganese-deficient plants were undertaken

plant proteins. If such is the case, this effect would be of great interest in animal and human nutrition, especially since deficiencies in trace elements are widespread[3], as is infant protein malnutrition (kwashiorkor), which appears to be primarily the result of amino-acid deficiency[4].

In a pilot study, beans (variety, Victory Dwarf Bush) were grown on Robbins's nutrient solution[5], and on this solution lacking in boron, copper, manganese and zinc respectively. They were harvested when the first fruits appeared, and the proteins were extracted according to the method of Lugg[6]. The proteins were hydrolysed for 12 hr. in 6 *N* hydrochloric acid and the amino-acid content of the hydrolysate was estimated by a semi-quantitative chromatographic method devised by one of us (H. E. S.). The results are recorded in Fig. 1.

There are indications in this preliminary investigation suggesting that beans grown in a copper-deficient medium have a higher concentration of threonine and perhaps a lower concentration of valine in their protein than normal, whereas beans grown in a zinc-deficient solution have proteins with a very low level of glycine and perhaps *iso*leucine. Confirmatory experiments are in progress on these and other plants.

We acknowledge the technical assistance of Misses H. Lenz and N. Posthumus.

Retention of Food Residues in the Midgut by Nymphs of the Milkweed Bug, *Oncopeltus fasciatus* Dall.

During experiments on the nutrition of *Oncopeltus fasciatus*, in the course of which both nymphs and adults ingested solutions containing a fine suspension of Chinese black, it was noticed that only the adults voided black fæces, and that newly moulted adults voided a particularly thick black mass within two days of ecdysis. In a confirmatory experiment, the insects were reared from the egg on milkweed seed and a water-suspension of Chinese black, and their excreta were collected on the filter paper shown in Fig. 1. By the time the first adults had appeared, only watery material had been excreted, whereas three days later, when nearly all had moulted, black fæcal masses were evident.

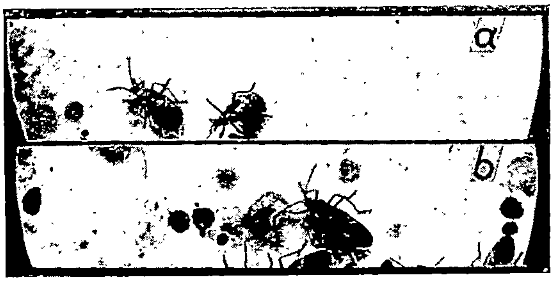

Fig. 1. The accumulated excreta of *Oncopeltus* reared on milkweed seed and a water-suspension of Chinese black: (*a*) just before and (*b*) after the majority had become adult

Examination of the nymphs showed that particles of Chinese black became concentrated in the third region of the midgut. It was also found that in mature nymphs which had fed on an abundance of milkweed seed, whether or not they had ingested Chinese black, this region was distended, had a flourishing bacterial flora, and contained a large droplet of oil. The short, narrow region (which has been called a 'fourth stomach'[1]) connecting the third region of the midgut to the 'pylorus' appeared, at this stage, to be histologically fully formed, but closed, although traces of a lumen could be made out along most of its length. In adults, the third region of the midgut did not reach the dimensions of that in the mature nymph, its bacterial flora was greatly depleted, and it was never found to contain a droplet of oil.

It appears, therefore, that in *Oncopeltus* the residues of nymphal meals accumulate in the third region of the midgut, to be voided soon after the final ecdysis. This does not seem to have been recognized previously, possibly because the nymphs excrete drops which contain reddish-brown solid matter, and these can be mistaken for true fæces, although they lack the thicker consistency of the latter and almost certainly originate entirely in the Malpighian tubes.

Many phytophagous Heteroptera possess special features associated with the last region of the midgut, such as cæca or inwardly directed filaments[2], which are lacking in *Oncopeltus*. It would be interesting to know, therefore, whether, in these cases, food residues are also retained in the nymphal midgut, since it is possible that the retention in *Oncopeltus* is concerned with ensuring the efficient extraction of nutrients from a simpler form of gut.

Composition of the Cell Wall of *Staphylococcus aureus* 209P

Recently, Park and Strominger[1] assumed that uridine-diphosphate compounds extracted from cells of *Staphylococcus aureus H* treated with penicillin are the precursors of the cell wall, because the cell wall and one of their compounds contained muramic acid, alanine, glutamic acid and lysine in the ratio of 1 : 3 : 1 : 1. But the cell wall also contained glycine (ratio 3 : 8).

We found[2] that similar uridine-diphosphate compounds were accumulated in another strain of *S. aureus* treated with penicillin, but these compounds contained five amino-acids: alanine, glycine, lysine, aspartic and glutamic acid in various combinations. As it seems probable that there is a certain variation in the amino-acid composition of cell walls among different strains of a single bacterial species[3], a study was made of the amino-acid composition of the cell wall of the present strain to confirm the assumed correlation between the accumulated compounds and cell walls.

Table 1. Amino-acid Content of Hydrolysates from the Bacterial Cell Wall of *S. aureus* 209*P*, expressed in No. of Molecules (Muramic Acid referred to as 1)

	Molecules		Molecules
Muramic acid	1·0	Aspartic acid	0·6
Alanine	1·6	Leucine	0·8
Lysine	1·0	Serine	0·7*
Glutamic acid	0·8	Threonine	0·3
Glycine	2·3	Valine	0·4

* This is probably a maximum value, since serine was only incompletely separated from glycine on the paper chromatogram.

Using the method of Cummins and Harris[4], cells of *S. aureus* 209*P* were ruptured with a Mickle disintegrator, the homogenate was centrifuged off the intact cells at 3,000 r.p.m., and the supernatant was further centrifuged at 10,000 r.p.m. The precipitated cell-wall fraction was treated successively with trypsin and pepsin, and hydrolysed with 6 *N* hydrochloric acid for 6 hr. at 120° C. Amino-acids in the hydrolysate were separated by two-dimensional paper chromatography using the method of Levy and Chung[5]. Ninhydrin-positive spots were cut out from the paper, eluted, and determined by the method of Rosen[6].

As shown in Table 1, not only muramic acid, alanine, lysine and glutamic acid but also glycine, aspartic acid and leucine (and/or *iso*leucine) were predominant. The undigested cell-wall fraction contained considerable amounts of valine and threonine, and the whole cells contained also proline, phenylalanine, histidine, methionine and tyrosine. This evidence shows that the same five amino-acids are found both in the cell wall and in the present compounds as main components. Furthermore, it was found that the main species of peptides linked with uridine-diphosphate-N-acetyl muramic acid were peptides composed of three alanine, two lysine and one glutamic acid residues, and of two alanine, two lysine, two glycine, one glutamic acid and one aspartic acid residues (Ito, E., Ishimoto, N., and Saito, M., unpublished work).

This evidence seems to support the assumed correlation between the accumulated compounds and cell walls.

Sagitta as a Host of Larval Trematodes, including a New and Unique Type of Cercaria

It has long been known that *Sagitta* may occasionally foster young trematodes, but we have learned very little since Müller, Busch, Leuckart and Pagenstecher made discoveries of this kind more than one hundred years ago. During the present century, Miss M. V. Lebour found two species of Digenea in *Sagitta bipunctata*[1]. Small *Derogenes varicus* (Hemiuridae) were seen near the ovary, generally singly, and post-larval *Opechona bacillaris* (Allocreadiidae) were seen in the gut as well as near the ovary, indicating that migration into the cœlom takes place through the wall of the intestine. Young forms similar to *Derogenes* have been found in the body cavity of unspecified chætognaths in South Australia, and small yellow cercariæ in the cœlom of *Sagitta enflata* were recorded but not described. Small appendiculate Hemiurids have been seen in *S. elegans* at Woods Hole and in *S. enflata* from the Bay of Algiers, and forms identified as small *Hemiuris communis* have appeared in *S. elegans* and *S. setosa* from Northumbrian plankton. Young forms of a rarer trematode—some unnamed member of the Accacoeliidae and possibly a species of *Tetrochetus*—have been found in *S. enflata* from the Indian Ocean near Madras[2].

Any trematode larvæ which gain entry into *Sagitta* may, it seems, with equal facility enter planktonic cœlenterates and copepods, and post-larval Hemiurids, Accacœliids and other Digenea have been found in such hosts. Heavy infections have been reported in siphonophores. In an infection of *Physalia utricula* with an unnamed Accacœliid near Japan, "les plus petits spécimens . . . de 5 mm. de long, ont déjà abrité un grand nombre de parasites dans leur polypes en développement, ainsi que dans diverses parties de leur poche aérienne"[3]. It is difficult to see how a fish could be infected through the agency of such a virulent vector, but it is evident that close co-operation between students of the plankton and parasitologists is necessary for the acquisition and study of the life histories of some of these elusive trematodes.

By the kindness of Dr. John Colman, I have been privileged to examine a number of parasitized *Sagitta* collected on the *Rosaura* Expedition[4]. Two specimens of *S. tenuis*—one from Barima River, Morowhana, and the other from Demerara River, Georgetown—contained a small appendiculate Hemiurid, which is probably a species of *Hemiuris*, and a very young larval cestode respectively. One *S. hexaptera* from the northern edge of the North Equatorial Current contained numerous multinucleate, non-helminthic parasites which are as yet unidentified. Twelve other *S. hexaptera*, collected in various localities in the Caribbean—between Cuba and Jamaica, off Roatan Island, some 250 miles N.N.W. of Colon, and off Puerto Columbia—contained a total of 15 larval trematodes of the same kind. Three hosts had two parasites each, the remaining nine hosts one apiece. Two of the larvæ were located in the intestine, the remaining 13 in the body cavity.

These larvæ have been seen only once hitherto and they are cercariæ, not metacercariæ. Each has two cylindrical posterior appendages with rounded distal extremities and very narrow connexions with the body (Fig. 1). They are undoubtedly identical with the forms called *Metacercaria owreae*, but they reach a larger size and show greater variability. The range of length × breadth is 0·3 × 0·2–1·2 × 0·7 mm., that of diameters of the oral and ventral suckers 0·07–0·24 mm. and 0·12–0·37 mm. The posterior appendages are not almost exactly half as long as the body in large and small specimens alike, as previous measurements indicated[5]; instead, they are of extremely variable length (0·25–1·45 body-length) and not proportionate to the size of the body.

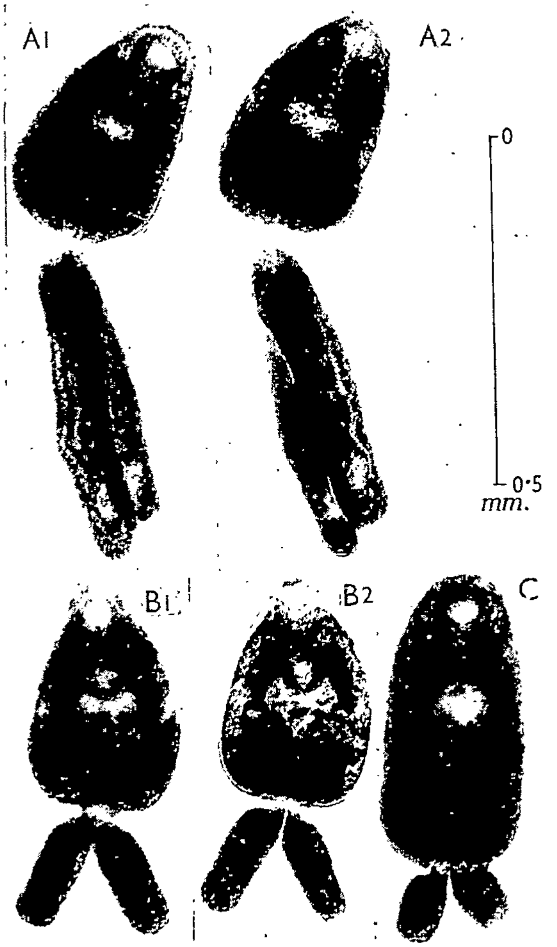

Fig. 1. *A*, *B* and *C*: three cercariae from three *Sagitta hexaptera* taken 250 miles north-north-west of Colon. In *A*1 and *B*1 the focus is on the ventral sucker; in *A*2 and *B*2 on the pharynx and the gut caeca. Actual body-lengths: *A*, 0·34 mm.; *B*, 0·33 mm.; *C*, 0·43 mm. Note the varying length of the posterior appendages; 0·4 mm. in *A*, 0·2 mm. in *B* and 0·1 mm. in *C* (approx.)

I can confirm the observation that a prolongation of each cæcum extends into the corresponding appendage—so that the term 'tail' is inadmissible—and I affirm that the corresponding adult must therefore possess a pair of anal openings. This unusual condition is known in only a few trematodes, but among these are the seven genera of the Accacoeliidae[6], and in this instance it must arise as a consequence of loss of the appendages during post-larval development. Another notable character, not observed hitherto, is the existence of short anterior extentions of each cæcum in the form of six very short and rudimentary diverticula, which form a kind of rosette at the tip. These are indications that this larval Accacoeliid probably belongs to the genus *Accacladocoelium* Odhner, 1928, but to which of four known species is uncertain because of the state of immaturity, although *A. petasiporum* Odhner, 1928, may be ruled out by the form of the ventral sucker. Older specimens with shrunken appendages or without appendages show peculiarly fine annulations indicative of *A. nigroflavum* (Rud., 1819).

New specimens of *Cercaria owreae* will not be easy to find, unless the following point regarding distribution proves helpful. Hitherto, only 8 specimens were found in 5,767 specimens of *Sagitta enflata*, *S. hexaptera* and *S. lyra*. The total incidence of infection was given as 0·14 per cent, the incidence for respective species 0·09, 0·14 and 1·15 per cent, no other figures being given. My specimens were obtained from 290 *S. hexaptera*, but 109 hosts of this aggregate which were collected off the north coast of Brazil and in the Central Atlantic did not contain any parasites; all 15 larvæ were obtained from 181 *S. hexaptera* collected in the Caribbean localities specified. Moreover, no parasites were found in 141 *S. enflata*, 110 *S. lyra* and 167 *S. maxima*, which are all transparent species in which any parasites could have been readily seen. The *Rosaura* hauls of *S. hexaptera* were made in open nets between 1,250 m. and the surface, although this is a species living mainly between the surface and 100 m. The first intermediate host of this trematode is presumably a bottom-dwelling mollusc of coastal waters, and the posterior appendages are probably organs of flotation which bring emergent larvæ into the realm of the plankton. The re-appearance of the pelagic larvæ may be anticipated in the Caribbean plankton and that of the Florida Current, probably also in that of the Gulf of Mexico and other localities. They must be sought as free forms, as parasites of species of *Sagitta* and as parasites of other planktonic animals such as coelenterates and copepods. The definitive host is most probably the sunfish *Mola mola* (L.) but it may well be some other oceanic fish which feeds on plankton. Infection will result from the ingestion of planktonic vectors containing larvæ, possibly from the ingestion of free forms.

I wish to thank Mr. A. T. Green of King's College for taking the photographs.

The Saw-Fish of Sierra Leone

There are three species of saw-fish which are occasionally caught along the coast of Sierra Leone. These are *Pristis pectinatus* (Latham), *Pristis pristis* (Linn.) and *Pristis peroteti* (M. and H.). The majority of captures have been made within the rivers, river mouths and from the open beaches; but as few of the captures have been subjected to any critical examination, practically nothing is known about the habits of saw-fish in Sierra Leone waters.

According to Copley[1], *Pristis pectinatus* and *Pristis peroteti* regularly ascend quite a long way up the Sherbro River when the river is in flood, and return to the sea on the falling of the waters. Whether this is a spawning migration has not yet been confirmed. The same species have also been caught in the Sierra Leone River, which is about 60 miles to the north of the Sherbro River, by the West African Fisheries Research Institute during trawling operations during 1952–57. They are also to be found more frequently in the Sierra Leone River when the river is in flood.

Saw-fish sometimes become entangled in the nets of the local fishermen, causing considerable damage to both nets and catch. For this reason, they are regarded as pests rather than a source of food, in spite of the fact that there is a ready market for the flesh. In the Keta district, Ghana, the 'saw' is removed and used for fetish purposes, being specially coloured alternately red, white and blue colours[2]. It does not, however, appear to have any religious significance for the fishermen of Sierra Leone.

During the course of a fish-marking cruise in May, a male specimen of *Pristis peroteti* was caught in the Sierra Leone River, about ten miles from the mouth. This fish weighed 257·6 kgm. and measured 4·42 m. from the tip of the 'saw' to the end of the caudal fin. The liver yielded more than 13 litres of oil, and within the stomach was found a 52-cm. 'whiting' (*Cynoscion brachygnathus*, Bleek), which was in a fair state of preservation and showed wounds caused by the 'saw'. There was a deep cut on the left side, about 19·5 cm. long, in front of the operculum and a stab wound in the flesh of the back in front of the dorsal fin. There was no other food material either in the stomach or the intestine of this saw-fish.

Although saw-fish may occasionally use the 'saw' as a defensive weapon, its main purpose is to obtain food. This it does by grubbing about on the bottom in its search for small fish and crustaceans lying buried there. It may also use the 'saw' as a weapon of attack, as the present instance shows; but it probably does so only rarely in the estuaries of Sierra Leone as the water is usually very turbid. In this connexion, it is interesting to note that the specimen under consideration was caught at the end of the dry season (May), when the waters of the Sierra Leone River are at their clearest.

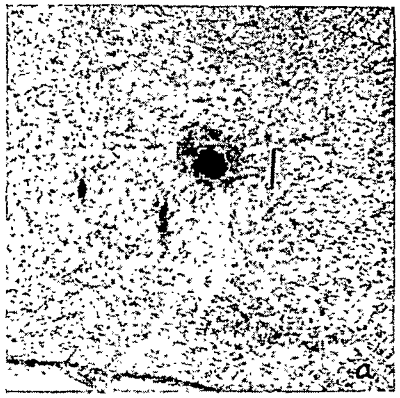
A Simple Microelectrode for recording from the Central Nervous System

Metal microelectrodes suitable for recording from single cells externally or after penetration have been described by various authors[1–3]. The procedures of Svaetichin[2] and Grundfest[1] call for special apparatus, and the method of Hubel[3], employing tungsten, in our hands gives rather noisy electrodes which are difficult to straighten. Steel electrodes, which have the advantages of low noise, low electrode potential, ease of straightening and, in particular, offer the possibility of accurate localization of the recording site, may be made as follows.

Stainless steel insert pins size 00, which are about 1·5 in. long (Clay-Adams Co.), are used. Using a filament transformer of 7 V. output, regulated by a variable auto-transformer, the terminal 1 cm. is thinned with alternating current against a carbon electrode dipped in concentrated hydrochloric acid. The surface of the acid is covered with xylol to limit the highly corrosive spray. The voltage is then reduced to about half and the tip quickly agitated up and down through the xylol–acid interphase. A highly polished and very sharp tip is produced. A terminal thickness of less than 0·5μ is readily obtained (Fig. 1*b*). Residual acid must be removed quickly to avoid pitting, so the electrode is quickly dipped in strong sodium carbonate solution and then successively in 1 per cent acetic acid, alcohol and xylene. Insulation is obtained in a manner similar to Hubel's technique[3]. While the electrode is wet with xylene, it is pushed beneath the surface of unthinned lacquer (Insl-*X E*33 clear, Insl-*X* Co., Ossining, New York), held beneath the surface for 30 sec., quickly withdrawn, inverted and allowed to dry at room temperature for 2 hr. It is then baked overnight at 60° C. Electrode resistance ranges between 5 and 100 megohms. Cells may be successfully penetrated, and extracellular spikes of up to 10 mV. with good rise times have been recorded from neurons in the hypothalamus, indicating reasonable electrode capacitance. The recording site may be marked by a current of about 2 μamp. for 15–30 sec. If the electrode is made the anode, a small amount of iron is lost. (The insulation may then be observed under the microscope as a transparent terminal core.) The animal is fixed in 10 per cent formalin with about 1 per cent potassium ferrocyanide added. A prussian blue spot is obtained. The large deposit shown in Fig. 1*a* was made by a much larger current (100 μamp. for 10 sec.), but this is unnecessarily large.



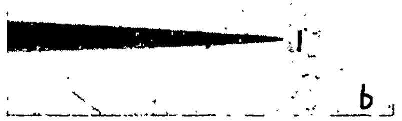


Fig. 1*a*. Site of recording marked by prussian blue reaction. Two earlier tracks to right. Mark = 200μ (100 μamp. for 10 sec.)
Fig. 1*b*. Electrode tip. Oil immersion. Mark = 2μ

It may be noted that if the lacquer advised is not available, a lacquer of high viscosity with a tendency to form a surface pellicle rapidly is desirable. This avoids beading and, while the electrode is inverted, the coat becomes thin as the central lacquer is still capable of flowing away from the tip beneath the surface pellicle. Lacquer shrinkage in the final setting determines the size of the exposed tip.

This work was aided by grants *B*-610 and *B*-485 from the U.S. Public Health Service.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (with a science degree with special qualifications and postgraduate experience in entomology or helminthology) in Zoology—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (October 10).

Lecturer (Grade III or II) in the Department of Civil Engineering—The Registrar, The University, Bristol 8 (October 13).

Lecturers (2) (with experience of applied electronics or of electrical plant and control systems) in Electrical Engineering—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (October 13).

Demonstrator (primarily zoological) in the Department of Biology—The Registrar, University College of North Staffordshire, Keele, Staffs (October 14).

Readers (2) in Physics—The Registrar, Panjab University, Chandigarh-3, India (October 15).

Vokes Research Fellow in the Department of Mechanical Engineering, to undertake research in the field of filtration, the separation of mixtures, or allied problems in fluid mechanics—The Secretary and Registrar, The University, Southampton (October 18).

Senior Research Officer or Research Officer (qualified zoologist with experience of fisheries research) in the Fisheries Research Unit within the Department of Zoology, University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Hong Kong, October 30).

Lecturer in Geography and Geology at the University of Natal, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, October 31).

Lecturer in Psychology at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, October 31).

Lecturer in the Department of Mechanical Engineering, University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, October 31).

Senior Research Fellows (2), and a Research Electronics Engineer in the Nuclear Physics Research Unit, Department of Physics, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, October 31).

Regius Chair of Materia Medica in the University of Aberdeen—The Private Secretary, Secretary of State for Scotland, St. Andrew's House, Edinburgh 1 (November 10).

Assistant Director of Research in General Surface Chemistry and Colloid Science—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge.

Assistant Physicist (with a first- or second-class honours degree in physics) at the Regional Laboratories, Royal Victoria Infirmary, Newcastle-upon-Tyne, for duties relating primarily to the uses of high energy radiation for medical purposes—The Secretary, Newcastle Regional Hospital Board, Newcastle-upon-Tyne 6.

Biochemist (with a degree in biochemistry, chemistry or physiology) in the Pathological Laboratory, Dulwich Hospital- The Group Secretary, Camberwell H.M.C., Dulwich Hospital, London, S.E.22.

Biochemist (with a knowledge of bacteriology) in the Bacteriology Department, for research on the genus *Lactobacillus* and similar organisms—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 58/26.

Engineer or Chemical Engineer, to improve design, and test equipment for extracting and processing leaf protein—The Secretary, Rothamsted Experimental Station, Harpenden, Herts.

Laboratory Technician (male, experienced in rock sectioning, etc., photography and general laboratory maintenance) in the New Department of Geology—The Secretary, The University, Exeter.

Lecturer (preferably with the ability to teach educational psychology) in Education in the Training Department—The Warden, Goldsmiths' College (University of London), New Cross, London, S.E.14.

Lecturer (with a degree or professional qualifications) in Spectroscopy; and Lecturers (2) in Electronics—The Principal, Brunel College of Technology, Woodlands Avenue, Acton, London, W.3.

Organic Chemists (2), and a Biochemist (with at least a first- or second-class honours degree and special aptitude for exacting preparative chemistry), to work on the labelling of complex compounds with radioactive isotopes—The Personnel Officer (1225Y/34), The Radiochemical Centre, Amersham, Bucks.

Physicist (with considerable experience in radiological protection work), to assist the Superintendent Health Physicist—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. 2012/34.

Physiologist (or Pharmacologist) (with a Ph.D. or equivalent experience of research, and preferably experience in pharmacological assay, experimental physiology or electro-physiology) with the Medical Research Council in the Department of the Regius Professor of Medicine, for research into various problems connected with neurohumoral physiology—The Regius Professor of Medicine, Radcliffe Infirmary, Oxford.

Postdoctoral Research Fellow (Biochemist or Chemist), to conduct investigations into the chemistry and biochemistry of carbohydrate sulphate esters—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff.

Regional Technical Information Officer (qualified in pure and applied science with a broad background of knowledge and experience)—The Principal, Welsh College of Advanced Technology, Cathays Park, Cardiff.

Research Assistant (with a degree in physics or a degree in geology and a good knowledge of physics) in Palæomagnetism, for work on the magnetic properties of rocks—The Registrar, The University, Birmingham 15.

Research Assistant (with a good first degree in botany or horticulture, and preferably research experience and a higher degree), for work on the physiology of flowering in carnations—Prof. O. V. S. Heath, Department of Horticulture, The University, Reading.

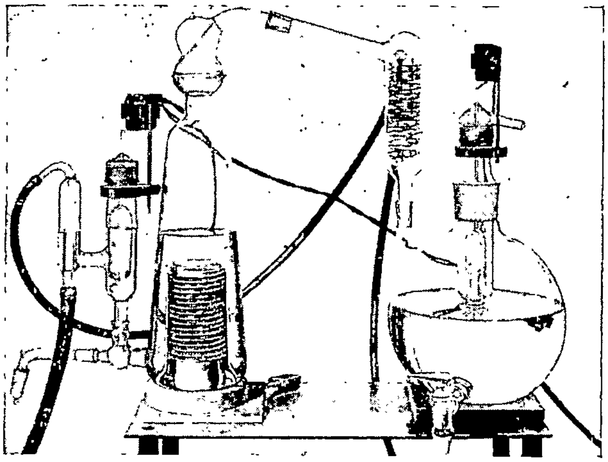
TAS/DO.9



This unique water still is in use in a number of research establishments and hospitals where water of the highest purity is essential

PRICE, complete with heater and all electrical equipment 230 volt (a.c. only)—**£25 - 10 - 0**
Inclusive of carriage and packing in U.K.

Obtainable ONLY from

L. V. D. SCORAH, M.Sc.
(Manufacturer of the "SCORAH" Blowpipe)
44 NORTHFIELD ROAD, KINGS NORTON,
BIRMINGHAM, 30. KINGS NORTON 1885

The SCORAH Automatic Electric all glass WATER STILL (patented)

Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost 3½d. per gallon at 1d. per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects or "burn out".

Assembly No retort stands or clamps are required. The 2½-in. diameter ball joint gives a strainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust. Phoenix heat-resisting glass. Interchangeable ground glass joints.

SPIRITUAL VALUES AND WORLD ORDER

SO far as men of science are concerned, the Lambeth Conference report* follows much the same pattern as its immediate predecessor. The bulk of the report is concerned with topics which are not the immediate concern of scientists, as such, though they will note the resolution which gratefully acknowledges the work of scientists in increasing man's knowledge of the universe. Many, no doubt, will welcome the summons to Christian people which follows "to learn reverently from every new disclosure of truth", as they will, too, the passage in the Encyclical Letter which admits that, "though the scientific and technological achievements of our age have encouraged a spirit of self-confidence which feels no need for God, yet underneath there is a spiritual emptiness"—and some will agree with the concluding words, "which only a faith in the reconciling love of God can satisfy".

This point of view is presented more fully in a passage in the report of the Committee on the Authority and Message of the Bible, in which, recognizing that the conflict which once existed between religion and science, through the misuse on both sides of their respective roles, has largely changed its ground, the Committee holds that a neutrality in which each ignores the other would be disastrous, and affirms its conviction that all knowledge comes from God and is to be reverenced as his gift. In all the discoveries of the sciences, God has a purpose that they may be used to reflect his glory in the world, and the Christian Church is summoned to learn from all new disclosures of truth. In that spirit the scientist should respect the further obligation of the Church to proclaim her message of the righteous God.

This outlook and temper are worth noting, because two sections of the report are concerned with problems with which men of science, as such, are equally concerned, and also because the solution of those problems may well lie, in part, in a harmonious partnership or understanding between the scientist and the Christian Church. First are the problems involved in reconciliation of the conflicts between and within nations, and second are the group of problems centring around the family in contemporary society. On the first, there is a dignified condemnation of racial discrimination in the resolutions and a survey of the racial problem, much of which, such as its condemnation of *apartheid*, is in keeping with representations which scientists, university teachers and administrators and others have made in a particular context, such as the autonomy of the South African universities. There are sensible references to industrialization and to what is required to eliminate industrial conflict and restore a lost sense of community and promote real freedom of communication and its maintenance. There are comments, too, on the rights of men and nations, and the sharing of material resources, which express an attitude of mind freely shared by men of science ; and the concluding section of this Committee's report, in which political conflicts are considered, merits close attention, because it poses a problem of action and of impartiality with which scientists are themselves familiar and which lies at the root of any attempt to apply scientific or technological knowledge impartially and objectively in public affairs.

Outstanding, however, in this field is the problem of peace, and especially the issues raised by the existence of nuclear and thermonuclear weapons. No attempt is made to conceal the existence of a division of opinion in the Conference itself, such as would be found in almost any representative body, Christian or non-Christian, regarding the use of nuclear weapons. The Encyclical Letter admits that while the use of such weapons is repugnant to the Christian conscience, and some regard their use in any circumstances as morally indefensible, others hold that as long as such weapons exist there are circumstances in which to use them might be preferable to political enslavement. The Conference believed that the abolition of nuclear weapons of indiscriminate effect and destructive power by international agreement is an essential step towards the abolition of war itself, and its resolution on modern warfare and Christian responsibility calls upon Christians to press through their governments, as a matter of utmost urgency, for the abolition by international agreement of nuclear bombs and other weapons of similar indiscriminate destructive power, and urges governments to accept such limitations of their own sovereignty as effective control demands.

The resolution further urges the governments of the leading nations of the world to devote their utmost efforts at once to framing a comprehensive international disarmament treaty, which shall also provide for the progressive reduction of armed forces and conventional armaments to the minimum necessary for the maintenance of internal security and the fulfilment of the obligations of States to maintain peace and security in accordance with the Charter of the United Nations. A further resolution, affirming the need for strengthening the United Nations, urges to that end that serious consideration be given to the revision of the Charter, to the more effective use of, and respect for, the existing processes of international justice, and to the creation of adequate means for enforcing its decisions. The resolution likewise commends whole-heartedly the work done under the ægis of the United Nations, whereby the skills and resources of member nations are made available for the benefit of the whole of humanity.

---

* The Lambeth Conference 1958. The Encyclical Letter from the Bishops together with the Resolutions and Reports. Pp. 171. (London: S.P.C.K.; Greenwich, Conn.: Seabury Press, 1958.) 7*s*. 6*d*.

This appeal for more enlightened support for the United Nations, so that it may become a more effective instrument of world peace and of that free co-operation between nations which is the condition of world order, is supported by a statement on peace and by a well-argued passage on conflicts between nations in the report of the Committee, over which Archbishop Joost de Blank of Cape Town presided. The statement lays its stress on the price which has to be paid for the establishment of peace and the creation of a world order of freedom and justice on which true peace can be based. It emphasizes that sacrifices will be demanded—of nations and of individuals: the foregoing of policies of self-interest which deny the interests of others, and the acceptance of at least some limitations of national sovereignty. Moreover, it is a long-term process: not in a day can trust replace mistrust, and partnership replace selfishness. Disagreements, rivalries and misunderstanding will long remain between nations and individuals, and a strenuous effort of mind and will is demanded of men if they are to understand and overcome, with a new urgency, the practical problems which divide the human family.

Much of this has been said, with increasing force, over the past thirty years, by scientists themselves as well as by others. The report enters also into the practical details which arise in the reconciliation of a world at so many widely differing stages of development, with such widely varying conceptions of law, freedom and standards of living. None the less, points are made which are worth re-emphasizing, and there is much to support the validity of the Committee's argument in one particular respect of the situation. Accepting the validity of the scientific method in its own domain and recognizing the wide range of benefits which science has brought to mankind, the Committee points out that science itself does not and cannot provide the key to the right use of the immense and rapidly increasing power it has placed in men's hands. The physical power of nuclear fission and the possibilities of psychological or genetic change are as much a threat to man's future life in this world as they are a potential source of great advantage to humanity.

Now that the world has been so progressively conditioned by a scientific climate of opinion as well as profoundly affected by the dazzling material achievements of science and technology, people have come to look upon any knowledge other than that obtained by scientific method as suspect. That is one reason for welcoming this report and the spirit in which it is written. It needs no more than the most cursory review of the achievements—and failures—of the United Nations to reveal how inadequate in international affairs is a scientific approach by itself. Something much more is required than the action that rational inquiry by itself may indicate, and whether or not individual scientists can share the hope of spiritual power in the task which this report might inspire, all men of goodwill should rejoice to welcome any co-operation that promises to assist the long slow task of educating public opinion, the removal of misunderstanding and distrust, and the encouragement of a forward-looking mind and readiness to discard old prejudices and try new ways. There should be a wholehearted response when the Christian Church seeks means whereby it can consult with scientists and political leaders about the many problems of ethics and conscience which may arise from the discovery and development of nuclear fission and fusion.

That in some of these fields scientists do not yet know the answers to the scientific and technical problems should make them the readier to co-operate with all who are open-minded and prepared to face changing situations without prejudice. Moreover, it must be admitted that we cannot even say whether a democratic society can establish and maintain world order. If indeed democracy, as we know it in the West, is to succeed in that task, the high moral and intellectual qualities which it demands of its citizens will require a much more effective system of public education than we have yet known in Britain, and moral and spiritual forces such as, it may be, only a religious faith can supply. To that task of education the Christian Church as well as science may well have decisive elements to contribute; nor need we be too pessimistic, in the perspective of time, if we look back merely far enough to visualize the chaos out of which the modern edifice of science has arisen in the past four centuries.

Already, indeed, the attempt to learn through the mistakes and early experience of both the League of Nations and the United Nations is well under way. When the American Bar Association met in London in July 1957, Mr. Herbert Brownell appealed deliberately for a system of law for the nations of the world, and visualized Anglo-American co-operation in developing the law of the nations so as to bind the countries of the world into solemn voluntary pacts, in contrast to unilateral exploitation by strong Powers. It is not, however, solely among the greater Powers that respect for law has to be fostered and the unilateral repudiation of agreements and contracts discouraged; and even here the existence of widely differing standards of value, of civilization and of ways of thought may at times make progress painfully slow. Nevertheless, it is encouraging to see that over the five years, 1951–56, with a grant from the Ford Foundation, Grenville Clark and Louis B. Sohn, with much assistance and comment from others, have worked out a comprehensive and detailed plan for the revision of the Charter of the United Nations*.

This plan, which has been issued this year by the President and Fellows of Harvard College, under the title "World Peace through World Law", and dedicated "to all those who seek the rule of law in world affairs", aims, therefore, at the promotion of the maintenance of world peace; but its immediate purpose is to contribute material for the world-wide discussions which must precede the establishment of truly effective institutions to prevent war. Its fundamental premise is that there can be no peace without world law, in the sense of law capable of enforcement as distinct from mere exhortation and injunctions, for the enforcement of which there is no effective machinery. It embodies also the conception that peace cannot be ensured by a continuous arms race, or by an indefinite balance of terror or diplomatic manœuvre, but only by the acceptance of institutions corresponding in the world field to those which maintain law and order in local communities and nations.

---

* World Peace through World Law. By Grenville Clark and Prof. Louis B. Sohn. Pp. xxxvi+540. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1958.) 7.50 dollars; 60s.

These premises, on which are based a set of definite and interrelated proposals to strengthen the United Nations through the establishment of such legislative, executive and judicial institutions as are necessary to maintain world order under enforceable world law, are reflected in the comments of the Lambeth Conference Committee's report on the reconciliation of conflicts; and, as has already been suggested, the forward outlook which characterizes the report should make it easier for the scientist and the Christian churchman to work together in a task which is as vital to the progress of science as it is to the preservation of mankind. It could not be claimed that the report, or for that matter the plan which Grenville Clark and L. B. Sohn advance, is notably freer from vague thinking than most public discussions of the organization of world order, and some of the premises may be unrealistic and open to challenge. At least, however, the dynamic nature of the situation is clearly grasped, and the report and the recommendations are pervaded by a sense that the solution of our dilemma is not to be found in a stable or static society but in a dynamic position of balance or relative security.

Perhaps even more striking evidence of this open-minded and developing outlook—it is not new, for it occurs in the previous Lambeth Conference report of ten years ago—is to be found in the report of the Conference Committee which dealt with the family in contemporary society. That report, which has been described as the great liberal achievement of the Conference, raises issues other than those of peace and war, of nuclear disarmament, racial reconciliation and the co-operation of Christian and scientist; but it is cited here as conclusive evidence of the growth of common ground over the past decade, and of the extent to which the Christian Church is approaching the problems of the modern world in the spirit characteristic of the scientist in his quest for truth. Even those who cannot accept, at least in its entirety, the thought and conclusions that characterize a Christian assembly may well be glad to recognize the powerful support from such a quarter for policies and causes which they have themselves at heart, and which without spiritual and moral support are ever less and less likely to be attained.

CONTRIBUTIONS TO THE THEORY OF WATER WAVES

Water-Waves

The Mathematical Theory with Applications. By J. J. Stoker. (Pure and Applied Mathematics: a Series of Texts and Monographs, Vol. 4.) Pp. xxviii+567. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1957.) 12 dollars.

During and since the Second World War the study of water waves has been pursued with increasing interest both for its own sake and for its numerous applications in oceanography, coastal engineering and ship-building design. Prof. J. J. Stoker and his colleagues at New York University have made many theoretical contributions, and in this book an attempt has been made to combine them into a logical unity.

The first section of the book is introductory; there is a chapter deriving the basic equations for non-viscous, irrotational flow, and the boundary conditions for gravity waves. The conditions at the free surface are non-linear, and the author describes the two standard methods of approximation: the small-amplitude approximation, in which expansions are in powers of the ratio (wave-height/wave-length); and the shallow-water approximation, in which expansions depend upon the parameter (mean depth/l), where l is a typical horizontal length (not necessarily the wave-length). Parts 2 and 3 of the book which follow are devoted to solutions with the small-amplitude approximation and with the shallow-water approximation respectively.

Among the topics discussed in Part 2 are free and forced oscillations in water of uniform depth, waves on sloping beaches of constant gradient, and waves started from rest by a sudden impulse; also the pattern of waves caused by a moving point-pulse in two or three dimensions (the latter being Kelvin's ship-wave pattern). The problem of the diffraction of waves around a vertical wedge is also solved. The assumption of small amplitude for the waves, and of irrotational motion, permits the use of a linearized potential theory. Particularly in the problem of waves on a sloping beach, the author uses complex-variable theory to great advantage. Part 2 ends with a chapter on a linearized theory of ship motion, assuming a thin hull-shape.

Thus far the mathematical treatment is of a high standard of interest, and though experimental evidence is lacking no reader will have difficulty in accepting the conclusions (for waves of sufficiently small amplitude). However, the first chapter of Part 3, which deals with waves in shallow water, is somewhat more controversial. The author applies the method of characteristic curves (also used in gas dynamics) to the propagation of waves in water of constant or slowly changing depth. The theory is approximate and is only valid so long as the vertical acceleration can be neglected. Thus the approximation is scarcely likely to hold for waves near the point of breaking. Indeed, the whole region of validity of this approximation needs further examination. Also included in this chapter are a new treatment of the solitary wave theory, and an application of the shallow-water theory to gravity waves in the atmosphere.

The remaining chapter of Part 3 contains a study of roll waves, assuming an empirical law of turbulent friction. The theory has been applied with some success to flood waves in the Mississippi River.

Finally, in Part 4, the author has grouped together two pieces of work under the heading "problems in which free surface conditions are satisfied exactly". The first of these is a version of Levi-Civita's proof of the existence of permanent waves (of sufficiently small amplitude) in deep water. The proof is slightly shorter than Levi-Civita's, but relies on more sophisticated techniques in function-theory. The other problem treated in this chapter is the flow resulting from a breaking dam (strictly speaking only the initial flow, for the solution is carried only as far as the terms in t^2).

For lack of space, many interesting and important topics have had to be omitted. For example, there is no mention of surface-tension waves, internal waves, or standing waves of finite amplitude, and with the exception of Chapter 11 the interesting effects of viscosity are completely neglected. Other developments, such as the statistical theory of sea waves and the theory of cnoidal waves (which really fills the gap between the small-amplitude theory and the shallow-water theory), are mentioned only in passing. Nevertheless, in those subjects that are discussed more thoroughly the reader will find many useful references.

The book as a whole is written from the point of view of the mathematician; greater attention to the physics (as for example in the case of breaking waves) would have been desirable as well as, more generally, a closer comparison with observation. Nevertheless, Prof. Stoker has produced, if not a classic, yet a book of considerable interest in a rapidly expanding field.

M. S. LONGUET-HIGGINS

ENCYCLOPÆDIA OF PHYSICS

Handbuch der Physik

Herausgegeben von S. Flügge. Band 40: Kernreaktionen I. Pp. vi+553. 128 D.M. Band 42: Kernreaktionen III. Pp. vii+626. 135 D.M. (Berlin: Springer-Verlag, 1957.)

IN Volume 40 a general account of nuclear reactions, levels and spectra by Prof. W. E. Burcham covers the light nuclei up to mass 40, while the same topics are dealt with for heavy nuclei by Dr. B. B. Kinsey. Almost all the experimental work referred to in these two chapters falls into the energy region below 50 MeV. The high-energy region of nuclear reactions is surveyed by Dr. A. Wattenberg, while the basic nucleon–nucleon interactions are treated in their theoretical and experimental aspects in Volume 39 of the series by Drs. L. Hulthen and M. Sugawara. Prof. J. Rainwater has contributed a section on resonance processes by neutrons. The general theory on nuclear reactions by G. Breit and collaborators can be found in Volume 41 (Nuclear Reactions II).

Prof. Burcham writes with his customary lucidity and erudition, about 20 pages of an excellent introduction to the current theories summarizing nucleon–nucleon interactions, models, coupling schemes and the general theoretical features of reactions; this is followed by a chapter on experimental methods for studying energy-levels, always giving just enough theoretical background to produce a happy blend useful to the consultants of this "Handbuch". Dr. Kinsey's contribution comprises a monumental and excellent monograph on nuclear reactions of the more complex nuclei and their levels and spectra. It is well written and, most important, the material is critically surveyed, an onerous task in view of the enormous literature. In view of the discriminating approach it is stimulating; suggestive of ideas and will no doubt be much consulted by research physicists. It is not quite clear to the reviewer why the editor included an article on resonance processes by neutrons, since this subject-matter could have been included in Dr. Kinsey's and Prof. Burcham's article. (See Fig. 33 and Fig. 15 of Dr. Kinsey.) As it is, Dr. Rainwater's section is authoritative, though not too well balanced, dealing almost exclusively with total cross-sections. There are too many graphs of a similar character and three derivations of the Breit–Wigner formula. The last of these could have been left to Volume 41 in "Nuclear Reactions II", where it will presumably be found again in Prof. Breit's article. Dr. Wattenberg's section on high-energy processes is a useful summary for a research physicist working in the field. The article contains a chapter on mesons and their interaction with nuclei, though meson physics proper is dealt with in Volume 43.

The contents of Volume 42 are made up of the following contributions: "Nuclear Isomerism" by Dr. D. E. Alburger (Brookhaven National Laboratory); "Alpha Radioactivity" by Prof. I. Perlman and J. O. Rasmussen (University of California); "The Transuranium Elements" by Dr. E. K. Hyde and Prof. G. T. Seaborg (University of California); "The Nuclear Photoeffect" by Dr. G. R. Bishop (University of Oxford) and R. Wilson (Harvard University); "Angular Correlations" by Prof. S. Devons and L. J. B. Goldfarb (University of Manchester); "Oriented Nuclei" by Dr. R. J. Blin-Stoyle and Dr. M. A. Grace (University of Oxford).

It is a pleasure to be able to say that all the articles in this volume are of the highest standard scientifically and didactically. To have been able to convince the participating authors to undertake such an arduous task confers great merit on to the editor. Who would have been able to cover the two chapters on alpha activity and transuranium elements better than the members of the Berkeley Radiation Laboratory, where so much of the research reported has been done under the inspiring leadership of Prof. G. T. Seaborg. The progress in this field is a spectacular monument to the benefits to science resulting from the development of reactors and accelerators. Forecasting the properties, chemical and physical, from systematics has reached a high state of perfection, and the progress in our ideas on nuclear models stands out clearly, the overwhelming evidence being due to artificially produced nuclei.

Dr. Alburger's article on nuclear isomerism is a model of clear exposition, full of useful information on theory and practice, so that not only the specialist can, in fact, use it. "Angular Correlations," by Prof. Devons and Dr. Goldfarb, covers in a uniform notation all the information one could desire in an excellent monograph (pp. 362–554). The mathematical treatment is, from necessity, abstract, but the results are aptly illustrated by correlation experiments drawn from the literature. This contribution illustrates the degree of theoretical knowledge expected from the experimentalist who embarks on a study of nuclear transition and the character assignment of levels. It is a pity that the teaching in the universities in Britain does not as a rule prepare the student particularly well in a field of such importance. "Oriented Nuclei," by R. J. Blin-Stoyle and M. A. Grace, offers a fine summary of a field where a great deal of important work can still be done. The chapter on the nuclear photoeffect (G. R. Bishop and R. Wilson) presents an able and complete survey of the field covering the experimental methods and the theoretical background for an adequate interpretation of the results. When the physicists have succeeded in producing monochromatic gamma-rays from the presently much-used continuous spectrum we can expect a great deal of further progress. The large intensities of the high-current accelerators hold much hope that this will be done soon.

On the whole, one can say that the field of experiments in nuclear physics and their interpretation in terms of theory have been well covered in Volumes 40 and 42, with the exception of beta decay and the fission process, which are to be found in Volume 41.

The references all through both volumes refer to publications which appeared roughly during 1950–56. Some reports on fields in rapid progress are therefore no longer completely up to date, such as the section on neutron resonance processes, in spite of an appendix. The standard of the "Handbuch" is well up to that of its predecessor published during the years 1926–29 by Julius Springer. It is remarkably free from obvious errors; but there is one misunderstanding: the strength function Γ_n^0/D does not refer to a single resonance but to an average over many resonances (Volume 40, p. 551). The absence of an author index is for some purposes regrettable. The value of this unique encyclopædia to the research physicist and university teacher is very great indeed.

E. Bretscher

ALL THE ENZYMES

Enzymes

By Dr. Malcolm Dixon and Dr. Edwin C. Webb. Pp. xviii+782 (12 plates). (London: Longmans, Green and Co., Ltd.; New York: Academic Press, Inc., 1958.) 90*s*. net.

THIS is one of the finest books that has appeared on the topic of enzymes. It is probably the first to maintain properly the tradition set by J. B. S. Haldane's "Enzymes" of 1930. Dixon and Webb proceed from that definitive treatment of enzymes with adequate mathematical presentation of enzyme kinetics and with concise discussions of properties of enzymes, their isolation, their specificity, their reaction mechanisms, etc., so that both students and research workers can obtain a comprehensive picture of the current status of our knowledge of enzyme action. In these days of 'brainstorming' and 'team' approaches, it is most encouraging to see the excellent and deliberate work of these highly qualified scholars, proving that, in their own terms, "the more old-fashioned type of book has advantages in continuity and consistency of treatment". This volume will surely be the standard reference work on enzymes for a number of years to come and will serve as a point of departure for many monographs on specialized topics in enzymology.

In addition to their extensive integration and categorization of the properties of enzymes, the authors have made a number of attempts to standardize various aspects of enzyme nomenclature and definitions of activities. While not all will agree with some of the classifications of enzymes, coenzymes, and cofactors, the proposals that have been put forward in this volume are logical and adequately documented. Since international commissions are now considering nomenclature and other aspects of enzymology, the material of this book will be extremely useful as a basis for decisions on controversial points, especially since the authors have attempted to maintain an objective point of view on these subjects.

The text is sufficiently extensive (670 pages) to deal comprehensively with the topic of enzymology, but because it is short, irrelevant and trivial aspects have, of necessity been eliminated. It opens with a striking " 'Atlas' of Crystalline Enzymes", which contains microphotographs of available enzyme crystals. In the second chapter, "Enzyme Techniques," the authors state the basic principles of enzymology in a language and form that can easily be understood by the student. This presentation continues through methods of enzyme isolation. Interesting discussions on "criteria of purity" of enzymes and "pitfalls in working with pure enzymes" are given. The book then launches into an extensive chapter on enzyme kinetics which can also be readily understood by the student. The plan of treatment follows that of J. B. S. Haldane and fortunately retains his terminology. Useful equations on the effects of enzyme and substrate concentrations, *p*H, temperature, inhibitors, etc., are included. The reviewer would like to note in passing that this volume may well mark the high-tide in the use of algebra to obtain analytic solutions for equations of enzyme action: analogue and digital computers are advanced to a point where they may be used routinely in further mathematical investigations of enzyme systems.

The fifth chapter contains a magnificent 92-page table in which the enzymes are divided into two main categories: hydrolysing enzymes (221 entries) and transferring enzymes (359 entries). Each enzyme is assigned a number which is referred to uniformly throughout the book. Again, some degree of arbitrariness has been necessary to categorize enzymes in this manner. (It was pointed out to the reviewer that enzyme 173 should be re-located near enzyme 215.) The sixth chapter discusses enzyme specificity and includes detailed data on peptidases and glucose oxidase. The reviewer makes note of the fact that definitive studies of enzyme specificity require measurements over very wide ranges of reaction velocity constants (about 10^6).

In Chapter 7, "Enzyme Mechanisms," a number of current theories on this subject are discussed in detail. However, some of the pages devoted to chain reaction theories might have been better spent on mechanisms for which more experimental data are available. The eighth chapter, "Enzyme Inhibitors," is very complete in its treatment of isolated enzymes. The fact that the book is not intended to cover inhibitors of metabolism leads to an abbreviated treatment of inhibitors in this class. In the ninth chapter, "Enzyme Cofactors," the case for retaining the coenzyme nomenclature (Co-I, etc.) in place of DPNH, etc., is made by the authors. The classification of cytochrome *c* as a carrier and not as an enzyme will be found difficult to apply to a sequence of cytochromes, as in the respiratory chain. Also, the omission of cytochrome *a* from the respiratory chain and the acceptance of evidence for a 'shuttle' and a 'transit time' of cytochrome *c* between cytoplasmic reductases and mitochondrial oxidase may require some reconsideration. The treatment of cytochromes is somewhat below the high standards of the remainder of the book, but this may be caused by doubts in the authors' minds as to the degree to which these enzymes afford a complete explanation of cellular respiration (cf. p. 423). Also, the list of cytochrome oxidases (p. 207) needs some amendment: cytochrome a_1 is not specified and a photo-oxidase of undetermined nature is included.

Chapters 12 and 13 on enzyme systems and enzyme biology, respectively, propose to bridge the gap between the the action of isolated enzyme systems and enzyme functions in the living cell. A 32-page table of enzyme systems represents a useful attempt to achieve an integrated treatment of such systems. As may be expected, the scope of these chapters is somewhat restricted because no serious attempt is made to give a comprehensive review of metabolism as a whole.

The book concludes with a complete list of symbols and abbreviations and a most extensive bibliography, conveniently arranged in alphabetical order and containing 2,353 references. It also contains a detailed and effective index.

This book will be widely used by the student and the research worker; it is easy to understand, easy to use, and authoritative. BRITTON CHANCE

A RECORD "ZOOLOGICAL RECORD"

The Zoological Record, Vol. 92

Being the Records of Zoological Literature relating chiefly to the year 1955. Edited by G. Burder Stratton. Pp. vi+1852. (London: Zoological Society of London, 1958.) 160*s*.

THE present volume relating mainly to zoological literature of 1955 is an indication of the increasing amount of research work in the subject, for this is the largest volume in the history of the "Record". All the sections have now been brought up to date with the exception of Trilobita, which only includes literature for 1954. The delay of about two and a half years in the appearance of the "Record" is surprisingly short in view of the difficulties of publication, and the editors and recorders deserve the thanks of zoologists throughout the world for their invaluable service. It should be emphasized that the individual sections are issued separately as soon as they are ready for publication, so that these are available at a much earlier date than the complete volume. The sections Aves, Comprehensive Zoology and Porifera, for example, were issued in November 1956, less than a year after the literature to which they refer, and most sections were available in 1957.

There is very little change in the relative size of each section, Insecta still heading the list with 535 pages compared with 546 the previous year; then Mammalia, 129 pages, closely followed by Mollusca, Vermes, Protozoa, Arachnida and Aves; and in descending order, Reptilia, Pisces, Crustacea, Amphibia, Trilobita, Coelenterata, Echinoderma, Brachiopoda, Comprehensive Zoology, Protochordata, Bryozoa and Porifera.

A total of 1,963 new generic and subgeneric names is recorded, a drop of 450 on the previous year. It is of interest to compare the numbers in the various groups, which correspond more or less with the size of each section so far as invertebrates are concerned. In the vertebrates, however, Aves, Amphibia and Reptilia with only twelve, four and fifteen new names, respectively, would seem to be reaching a settled nomenclature, but in Mammalia there is the surprisingly high total of fifty-six new names, and in Pisces seventy-one.

The difficulty of inventing new names is well recognized, but the present list in many instances contains such involved and clumsy terminology as to arouse a certain regret that simpler and rather more elegant names could not have been devised.

The "Zoological Record" owed much to the work of Dr. Malcolm Smith, whose death occurred recently. He was sectional recorder of Reptilia and Amphibia for seventeen years and editor from 1938 until 1949, including the very difficult years during the War, when he still managed to maintain the publication of the "Record". EDWARD HINDLE

SYNTHETIC TAXONOMY

The Bladder Campions (*Silene maritima* and *S. vulgaris*)

By E. M. Marsden-Jones and Dr. W. B. Turrill. Pp. vii+378+44 plates. (London: The Ray Society, 1957. Sold by Bernard Quaritch, Ltd.) 30*s*.

THE detailed researches on *Silene maritima* and *S. vulgaris*, begun more than thirty years ago by Dr. Turrill and Mr. Marsden-Jones, are widely known as classics of 'synthetic' taxonomy. Hitherto, the results of these investigations have been available only in a series of thirty-four papers in the *Kew Bulletin*, extending over the years 1928 to 1957, and it has, inevitably, been a matter of considerable time and difficulty to obtain a comprehensive view of the subject. This great volume of work is now brought together, with the addition of previously unpublished data, in a well-illustrated book, a large part of which is occupied by the presentation, in a condensed form, of the evidence on which the general discussion of the last twenty pages is based.

To anyone interested in the wider aspects of taxonomy as revealed by a combination of experimental and 'traditional' methods this book will be invaluable. It shows not only how much can be found out about the history, relationships, ecology, genetics, morphology, anatomy and distribution—in a word the taxonomy—of two common species, but also how much remains to be found out, even after more than thirty years of hard work by two able and experienced investigators.

There remain, of course, large and untouched fields outside the scope of the present study, such as the comparative physiology of the various taxa recognized, but it must be evident to the most casual reader that no plant can be dismissed as common and uninteresting or even ordinary. It speedily becomes obvious on reading this book that any plant can keep a botanist fully occupied for a lifetime and still yield only an approximation to omega taxonomy.

Many years must elapse before knowledge of this kind can be accumulated about all the species of flowering plants, even in such a limited flora as that of the British Isles, but any information about the basis of variation, the kind of breeding-system and the factors which isolate and maintain the distinctness of related taxa has an immediate value to the taxonomist.

It seems, however, that for the foreseeable future we shall have, as the authors point out, to be content with a classification based mainly on the classical criteria of gross morphology, modified in small ways by experimental data. Such a system may indeed prove to be the most convenient all-purpose one in the long run, even should it become possible to make phylogenetic or physiological classifications for special purposes.

T. G. TUTIN

STUDIES IN BUSINESS ORGANIZATION

Business Enterprise

Its Growth and Organization. By Prof. Ronald S. Edwards and Harry Townsend. Pp. xvii+607. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1958.) 60*s*. net.

THE authors have produced a book on the growth and organization of business that is at once scholarly and immediately intelligible to the layman; this is no mean achievement. The book is based on a wealth of case material built up over the past twelve years. During that time evening seminars on industrial administration have been held at the London School of Economics, the main feature of each seminar being the discussion of a previously circulated paper written by an industrialist or Civil servant. The incorporation of 'potted' case histories from these papers and elsewhere without making the narrative disjointed has been skilfully done.

The book is divided into four parts dealing respectively with the birth and growth of firms, factors determining the size and specialization of firms, the Government and industry, and the future of industry in Britain. There is a steady and noticeable change of emphasis as one proceeds through the book away from the descriptions, explanations and analyses which dominate Part 1 and towards the exposition of what the authors strongly believe to be good for us, which—necessarily in view of its subject-matter—dominates Part 4. Thus, when we read in Part 3 that, "... the reader should be warned that he is dealing with two authors who believe that every extension of central power should be very amply justified before it is granted, and that the onus of proof should always lie with those who propose centralisation", we are merely receiving confirmation of a suspicion that has been building up over several chapters.

Parts 1 and 2 draw especially heavily on the case material referred to above, which provides numerous examples illustrating the developing theme; each of these Parts has several appendixes comprising papers which have been read to the seminar. Part 3 provides an admirable account of the relations between the Government and industry, and includes excellent chapters on Government organization of industrial research, the location of industry, the steel industry and the organization of nationalized industries.

The dust-jacket tells us that the book is addressed to students of industrial economics and government, and to practising business men. It will be surprising if it does not find favour with a much wider reading public than this. In particular, students of science and technology who intend to go into industry should find it a most worth-while addition to their shelves.

L. G. JAEGER

ARCHÆOLOGY OF SOUTH-EAST ENGLAND

An Archæology of South-East England

By Gordon J. Copley. Pp. 324+28 plates. (London: Phoenix House, Ltd., 1958.) 50*s*. net.

IT is stated on the dust-cover that the information contained in this volume can otherwise be found only in numerous scattered publications, many of them of a specialist nature, and that it is a book unlikely soon to be superseded. With these statements any reviewer must agree. Dr. Copley has studied widely and, so far as the limits of his space allow, has covered the ground of the wide area with which he is concerned. The author of such a work of compilation must of necessity begin by fixing in his mind the sort of public for whom he will be catering. I imagine Dr. Copley has written primarily for the instructed amateur. But the maps and, above all, the gazetteer will be welcomed by the specialist as well.

The work opens with some general chapters dealing with such problems as the amateur in archæology and the natural background. These are followed by chapters on periods—Palæolithic to Middle Ages—and in conclusion there is a study of locality and of place names, a bibliography and a gazetteer. In the period chapters there are distribution maps—necessarily of very small scale—and later in the volume, grouped together, will be found 28 half-tone illustrations. The early chapters depend, to a large extent, on Zeuner's work. He is a good guide, even though everyone does not agree with all he suggests—especially his dating. But for the instructed amateur the opening phases of the book will be found useful. The geo-chronology is, of course, far more complicated than could be dealt with in the short account which space allows, but a generalized picture is given. The Neolithic and Early Metal Age chapters, again within the limits of available space, are excellent. Naturally for the later periods, as so much more evidence has survived, the account has to be more sketchy. But Dr. Copley has managed to see the wood in spite of the trees.

Specialists will welcome the bibliography of local publications. So many local societies publish bulletins nowadays that it becomes difficult even to keep check of their names. In respect of the very valuable gazetteer of sites and finds, one can really only criticize the author for not giving any reference to where the finds were published. He says this could not be done without extending the gazetteer to an inordinate length. But the usefulness of the lists would have been enhanced tenfold if a hieroglyphic had been added to each reference. The hieroglyphics could have been associated with the bibliography. For example, take the "black beauty" from Reculver: palæolithic tools from this place are mentioned by cross-reference under Herne Bay, but no one interested in palæolithic tools from that site can follow up the reference or discover whether they were chance surface finds or the result of systematic excavation and investigation. Should the book run to a second edition it is to be hoped the author will give serious consideration to this very important matter. But it is not on a note of criticism that one wants to conclude. The work is, of its kind, excellent; a wide area is covered, and a good picture given of mankind's existence in the region over a long period of time. The author is to be congratulated.

Theory of Dielectrics

Dielectric Constant and Dielectric Loss. By Prof. H. Fröhlich. Second edition. (Monographs on the Physics and Chemistry of Materials.) Pp. viii+192. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 30*s.* net.

IT is now about nine years since Prof. Fröhlich's book "Theory of Dielectrics" was first published. It was intended mainly for applied scientists, but was also of great value to those working on the theory of the dielectric constant and its relation to atomic structure. This latter subject (dealt with in Chapter 2) is one which may appear simple, but there is a great deal of confusion and error about it, and we must be grateful that Prof. Fröhlich's exposition is now again available and we can see clearly expressed the relations between the various formulae such as the Kirkwood, Onsager, Clausius-Mosotti, and the conditions under which each is valid. The book also dealt with dynamical problems, and in particular the dependence of dielectric constant on frequency. This is also a very valuable chapter because the Debye equations, for example, are often wrongly used, and the conditions under which they are valid are here clearly stated.

In this second edition the main body of the book has not been changed (though the price has been increased by two-thirds), but three short additional appendixes have been added. The first two are additions to Chapter 2; the third is a brief preliminary account of the work on dielectric loss now being carried out by Sack and Gross.

A. F. DEVONSHIRE

Proceedings of the Second International Congress of Surface Activity

Edited by J. H. Schulman. Vol. 1: Gas/Liquid and Liquid/Liquid Interface. Pp. ix+521. 90*s.* Vol. 2: Solid/Gas Interface. Pp. viii+348. 75*s.* Vol. 3: Electrical Phenomena and Solid/Liquid Interface. Pp. x+621. 100*s.* Vol. 4: Solid/Liquid Interface (Washings, etc.), Cell/Water Interface. Pp. viii+352. 75*s.* (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1957.) Set of 4 volumes, £16; 50 dollars.

THIS Congress was described in *Nature* of August 3, 1957, and the Proceedings have now been published in four volumes with a slightly different arrangement from that suggested in the note on the Congress: Vol. 1 includes gas/liquid and liquid/liquid interface; Vol. 2, solid/gas interface; Vol. 3, electrical phenomena and solid/liquid interface; and the final volume deals with solid/liquid interface (washings, etc.) and cell/water interface. The washings, etc., in the title of the last volume are concerned primarily with laundering and the use of surface-active interfaces in connexion with suspensions of solids and liquids. These four volumes can be bought separately.

The classification has been on a scientific basis, but a very wide range of industrial applications is considered in addition to the main theme of detergency. Thus, froth flotation, lubrication, retardation of the evaporation of water and the many industries dependent on adsorption processes are among the topics considered.

The treatment in the papers of the Proceedings is uneven, as is obvious in the discussions that follow the individual topics treated in the different volumes. It would have been better had a more rigorous selection been made of the papers and particularly if each section could have been preceded by a reporter's summary. Nevertheless, the Proceedings give a most valuable and comprehensive interpretation of modern surface chemistry (and show how much physical chemistry can be included under this heading), with many applications in engineering fields, particularly in the realm of mass transfer.

Numerical Analysis

By Kaiser S. Kunz. Pp. xv+381. (London: McGraw-Hill Publishing Company, Ltd., 1957.) 60*s.*

THIS book is based on notes covering lectures given by the author at the Computation Laboratory of Harvard University during 1947–49. It covers the classical field of numerical analysis—finite differences, interpolation, numerical differentiation and integration, and the solution of equations.

There is an extensive treatment of partial differential equations, and the reviewer is glad to find that the author has presented the subject in proper historical form, due recognition being given to the pioneering paper of 1918 by Liebmann. It seems, for example, that it is not generally known that the approximate solution of Laplace's equation goes back to ideas of Boltzmann and Jacobi. The Liebmann process is compared with the more recently introduced relaxation method of Southwell, and it is pointed out that the latter is far superior for hand computation but loses a good deal of its advantage when used with an electronic computer.

One short chapter is devoted to integral equations, but there is no numerical treatment, the account being confined to the theory of the numerical solution. Most chapters conclude with a set of problems, and this, together with the author's style, not too verbose and not too condensed, will make the book a useful text for students.

L. S. GODDARD

Ptaki Ziem Polskich, Tom I

By Jan Sokolowski. Pp. 441+38 plates. (Warszawa: Państwowe Wydawnictwo Naukowe, 1958.) Cena zl. 80.

SOKOLOWSKI'S work on "The Birds of Poland" was first published in 1936, but the edition was well-nigh destroyed during the Second World War. This circumstance and the post-war alteration of the Polish frontiers has led the venerable author to publish a revised and re-written edition. This first volume of the work deals with the Passeres, Macrochires, Caprimulgi, Upupae, Meropes, Coraciae, Halcyones, Cuculi and Pici that are the residents, migrants and visitors of post-war Poland. The systematics and nomenclature followed are those of G. Niethammer, with a few changes according to G. P. Diemientjew. The text is well illustrated with drawings in black-and-white, coloured plates and photographs, but the low standard of production of some of the plates and most of the photographs is regrettable. The five glossaries in Polish and Latin, Russian, French, English and German are useful, but that in English contains many errors, which is surprising, as the English names in the text are given correctly.

This book is intended for both Nature-lover and ornithologist and gives accurate and penetrating records of biological observations, but there is no orderly, compact and generalized treatment of special topics such as habits, breeding and distribution. The style of writing is fluent, but so wordy and rambling that, unfortunately, it is necessary to search for much of the valuable information the book undoubtedly contains.

AIR SHOWERS OF SIZE GREATER THAN 10^5 PARTICLES*

(2) ČERENKOV RADIATION ACCOMPANYING THE SHOWERS

By M. H. BRENNAN†, J. MALOS, Dr. D. D. MILLAR and C. S. WALLACE

The F.B.S. Falkiner Nuclear Research and Adolph Basser Computing Laboratories, School of Physics‡,
University of Sydney

In a series of experiments at Harwell and the Pic du Midi, Jelley and his collaborators have demonstrated the feasibility of detecting the Čerenkov pulse associated with an air shower against the background of the night sky luminosity[1-4]. Later experiments by Nesterova and Chudakov[5] have confirmed the results obtained by Jelley and Galbraith. Since the Čerenkov light is emitted throughout the atmosphere, experiments on this phenomenon are of considerable importance since they may lead to a method for investigating the longitudinal development of the air showers.

The early experiments of Jelley and Galbraith were confined to simple apparatus using a light receiver consisting of a parabolic mirror and a single photomultiplier at its focus. Small trays of Geiger counters placed at varying distances from the light receiver were used to detect the arrival of the air showers.

Jelley and Galbraith established that the pulses from the night sky, which were not identifiable as random fluctuations in the photocurrent of the photomultiplier, had an integral pulse-height distribution of the form:

$$R\,(\geqslant H) \propto H^{-1.6 \pm 0.1}$$

They further established that the rate of detecting the pulses in coincidence with a tray of Geiger counters decreased with increasing separation of the light receiver and the counter tray. It was also shown that the observed pulses had properties consistent with their being Čerenkov radiation from the electrons of the air showers. Contributions to the light from bremmstrahlung, recombination light and de-excitation light were found to be at least one hundred times smaller than the contribution from Čerenkov light[4,6].

The experiments which are described in this article were undertaken in order to investigate quantitatively the dependence of the Čerenkov light pulse on shower size and distance of the light receiver from the shower axis. Some preliminary results are also given on the angular distribution of the light. These studies are of particular importance in assessing the results of experiments, using light receivers of the type described by Jelley, to investigate anisotropy in the high-energy cosmic ray flux[3,7]. The article concludes with some comments on the applicability of air shower theory to the interpretation of the observed features of the Čerenkov light associated with air showers.

Experimental Arrangement

The light receiver is located near one end of an array of nine scintillation counters. (A complete description of the array, the method of recording pulse-heights and the method by which the size and location of the core of the shower are determined is given by Brennan, Millar and Wallace[8].) This arrangement enables us to make observations on showers of 10^5–10^7 particles the cores of which fall at distances of 0 to 60 m. from the light receiver.

The light receiver consists of seven photomultipliers with 2-in. diameter photocathodes (*E.M.I.* type 6260) clustered about the focus of a 44-in. diameter parabolic mirror. The focal length of the mirror is 18·6 in. This arrangement results in seven acceptance cones, each of half-angle approximately 3°, the axes of the outer six cones being inclined at angles of approximately 7° to the axis of the central cone, which is directed to the zenith. Tests on the optical properties of the mirror show that for angles less than 7° the circle of confusion is much less than the diameter of each of the photocathodes. For angles of about 10°, just on the outer edge of the acceptance cones, some coma in the radial direction away from the central axis is present. This does not affect the angular resolution of the instrument but may slightly decrease the gain of the outer photomultipliers for sources of small angular size.

The photomultipliers and mirror are housed in a specially constructed hut which has a plate-glass roof. A roller blind cover which is controlled by a time switch opens approximately one hour after sunset and closes one hour before sunrise. This ensures that the light-intensity incident on the photomultipliers is kept within safe limits. The time switch also controls the extra high tension to the photomultipliers.

Pulses from the photomultipliers are fed to individual pre-amplifiers mounted above the photomultipliers. A metal shield is inserted between the circuits to prevent pick-up between channels. The outputs from the pre-amplifiers are fed through coaxial line to the central recording station, where the pulse-heights in coincidence with the air showers detected by the scintillation counter array are recorded on punched paper tape[8].

Extra-high tension to the photomultipliers is supplied from a power supply which automatically adjusts the voltage so that each anode current is kept below 100 μamp. This figure is recommended by the manufacturer as an upper limit consistent with reliable operation of the tube. This procedure enables the detector to operate despite large fluctuations in brightness which occur when low cloud passes over the detector; reflexion from city lights may then cause an increase of a factor one hundred in the light flux incident on the photomultipliers.

---

* The first article in this series was published in *Nature* of October 4, p. 905.

† Present address: Palmer Physical Laboratory, Princeton University, Princeton, New Jersey.

‡ Also supported by the Nuclear Research Foundation within the University of Sydney.

Results from the light receiver are used only when the extra-high tension voltage (which is approximately inversely proportional to the seventh root of the general background intensity) indicates that there is no cloud overhead. This means that, for the events which are analysed, the high tension to the photomultipliers varies from 980 V. to about 1,180 V., which is the limit set by the power supply. These variations in voltage are taken into account by normalizing all pulse-heights to their equivalent value at 1,000 V. high tension. This normalization is carried out from previously determined gain-voltage characteristics of the photomultipliers.

The gains of the photomultipliers were aligned by using the night sky as a diffuse light source and adjusting separate potentiometers supplying high tension to the photomultipliers until the anode currents were the same for all photomultipliers. The gains of the pre-amplifiers were measured *in situ*, so that the overall relative gains of the seven channels were known to about 10 per cent accuracy.

In the present work no attempt is made to make an accurate estimate of the absolute gain of the system in terms of output voltage per incident photon. However, an estimate which is probably accurate to about 30 per cent was made from the manufacturer's figures on gain and photocathode sensitivity. It was found that, for 1,000 V. across the photomultiplier, 1 V. on the coaxial line corresponds to approximately 10,000 photons incident on the photocathode. A pulse is not considered significant in the present work unless it has a normalized height greater than 0·6 V. This rather high threshold is dictated by the high background level of illumination. It is chosen so that, under the worst possible conditions, the chance coincidence rate at the minimum level is only of order 1 in 10^3 events.

Light Pulse as a Function of Shower Size and Core Location

A series of experiments was first carried out with only one of the seven photomultipliers in operation. The central photomultiplier was chosen, and events analysed only when the chart on which the high tension supplied to the photomultiplier was recorded showed that there was no cloud overhead.

A total of 206 showers was recorded for which the above condition was satisfied, and for which shower size and core location could be obtained from the response of the scintillation counter array. Of these events, 22 were accompanied by a pulse from the central Čerenkov photomultiplier of height greater than the minimum acceptable level.

No functional relationship was observed between the size of the Čerenkov pulse and the shower size, N, and the distance, R, of the core of the shower from the light receiver. Indeed, a number of events were obtained in which a large Čerenkov pulse was associated with responses in the scintillation counters too small to permit an estimate to be made of the size of shower and location of core. These pulses may be due to small showers (10^3–10^4 particles) falling very close to the Čerenkov detector or, as will be discussed later, to very large showers striking the ground far from the air shower array but passing through the acceptance cone of the receiver high in the atmosphere.

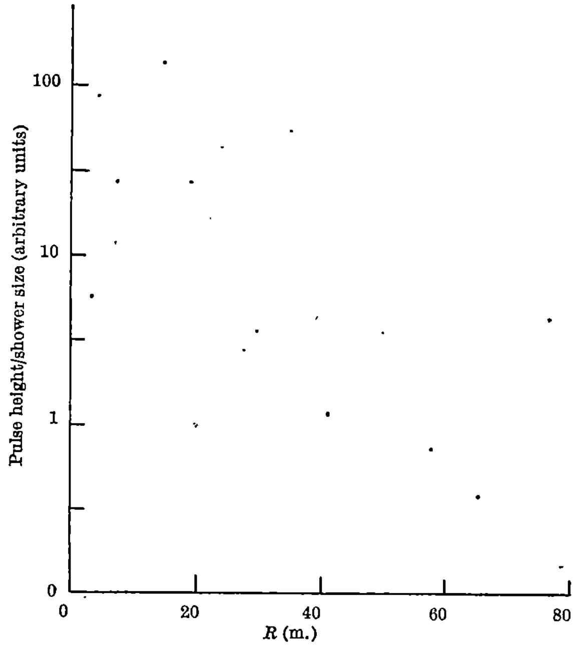

Fig. 1. Dependence of the reduced Čerenkov pulse-height on the distance, R, of the light receiver from the shower core

Fig. 1 shows the ratio, C/N, of Čerenkov pulse-height to shower size as a function of R, the distance of the core of the shower from the light receiver, for the 22 events in which a Čerenkov pulse was recorded. We note that, although there is no functional relationship between C/N and R, the maximum value of this 'reduced pulse height', as we shall call it, is a decreasing function of R.

It is of interest to investigate the fraction of showers detected by the array which were accompanied by Čerenkov pulses of different heights. An analysis of this kind is complicated by the fact that we are forced to reject pulses the heights of which are less than a fixed level (0·6 V.) independently of shower size. Thus, a pulse of, say, 1 V. from a shower of size 10^6 particles is accepted and has a reduced height of $1/10^6$, whereas a pulse of 0·5 V. from a shower of size 10^5 particles is not recorded although it has a reduced pulse-height of $5/10^6$.

In Table 1 are presented the values of the ratio of the number of showers with reduced pulse-heights greater than 10, 20, 40 and 80 (arbitrary units) to the total number of showers recorded by the scintillator array during the time of observation and in the absence of cloud. (We shall refer to such a ratio as a fractional rate.) The showers are classified according to the distance of their cores from the Čerenkov detector. The units used for the reduced pulse-heights are such that a pulse of 10 arbitrary units, associated with a shower of 10^6 particles, is equivalent to approximately 25,000 photons m.$^{-2}$ incident on the light receiver.

In compiling Table 1 we have treated the problem of a fixed minimum acceptable pulse-height by calculating upper and lower limits for the fractional rates. The lower limits are obtained by assuming that all events with normalized pulse-heights not greater than the minimum acceptable level of 0·6 V. have, in fact, zero pulse-height. Upper limits to the

The figures in brackets are the actual numbers of Čerenkov pulses recorded

R (m.)	0–20	20–40	40–60
$C/N \geqslant 10$	0·17–0·28 (9)	0·12–0·38 (12)	0·20–0·30 (1)
$\geqslant 20$	0·11–0·19 (6)	0·10–0·26 (10)	0·02–0·15 (1)
$\geqslant 40$	0·08–0·11 (4)	0·04–0·04 (4)	0·02–0·02 (1)
$\geqslant 80$	0·06–0·06 (3)	0 (0)	0 (0)
Total number of events	53	99	54

fractional rates are obtained by assuming that all such events are accompanied by a Čerenkov pulse of height equal to the minimum level of 0·6 V.

For part of the operating time during which the above-mentioned 206 showers were recorded, one of the off-centre photomultipliers was also in use. The axis of its acceptance cone was inclined at 7° to the vertical and was directed over the centre of the air-shower array. During this time 56 showers were recorded. Of these, 1 was accompanied by a Čerenkov pulse from the central photomultiplier alone, 7 were accompanied by a pulse from the off-centre photomultiplier alone, and 9 were accompanied by simultaneous pulses from both. Results from the 16 off-centre photomultiplier events are presented in Table 2 in a manner similar to those obtained from the central photomultiplier.

Table 2. Fraction of Showers accompanied by a Čerenkov Pulse from the Off-centre Photomultiplier as a Function of the Distance of the Light Receiver from the Shower Core and the reduced size of the Čerenkov Pulse

The method of presentation is similar to that used in Table 1

R (m.)	0–20	20–40
$C/N \geqslant 10$	0·29–0·43 (6)	0·32–0·49 (10)
$\geqslant 20$	0·19–0·29 (4)	0·20–0·34 (7)
$\geqslant 40$	0·19 (4)	0·11 (4)
$\geqslant 80$	0·19 (4)	0·11 (4)
Total number of events	21	35

Despite the rather wide spread between the upper and lower limits to the fractional rates for both photomultipliers, it can be seen from the tables that the probability of detecting a Čerenkov pulse decreases fairly slowly with increasing distance of the light receiver from the shower core (in the range 0–60 m.) and decreases quite rapidly with increasing bias level (in terms of reduced pulse-height). We also note that the average fractional rate for the off-centre photomultiplier (16/56 = 29 per cent) is greater than that for the central photomultiplier (22/206 = 11 per cent). Also, the fractional rate does not decrease as rapidly with increasing bias-level in the case of the off-centre photomultiplier. We shall see later that this may be understood qualitatively in terms of the integrated particle flux in the respective acceptance cones.

Again, for part of the operating time three collinear photomultipliers were in use, resulting in three acceptance cones with coplanar axes, one inclined at 0° and two at 7° to the vertical. Three events were recorded in which all three photomultipliers gave simultaneous pulses.

Angular Spread of the Čerenkov Light

The results presented in the preceding section indicate that the height of the Čerenkov pulse does not bear a simple relation to the shower size, N, and the distance, R, of the light receiver from the shower core. A possible explanation for the occurrence of large fluctuations in the pulse-heights lies in the fact that the air-shower electrons do not all travel in a direction parallel to the shower axis; the Coulomb scattering of the electrons can lead to the emission of Čerenkov radiation from the shower at an angle to the shower axis considerably greater than the angle of emission from a single particle (1·3° at sea-level).

That light is indeed emitted with a large angular spread from individual air showers is indicated by the results presented in the previous section, where it was noted that coincident pulses from two, and even three, photomultipliers looking in different directions were not uncommon. In the case of the three-fold coincidences, the angular spread of the light must be at least 7°.

Further information on the angular distribution of the light was obtained from an analysis of 157 showers for which, in addition to an estimate of the shower size and core location, the direction of incidence of the shower axis was known. This latter information was obtained by a timing technique which has been described briefly elsewhere[9]. As in the investigations on the radial dependence of the Čerenkov light, only the central vertical-looking photomultiplier was used. We may therefore identify the angle of emission of the light (with respect to the shower axis) with the zenith angle of the shower axis (see Fig. 2).

Of the 157 showers analysed, 20 were accompanied by a Čerenkov pulse from the central photomultiplier. The events were first classified into two groups:

Group 1. Showers for which the minimum distance between the axis of the acceptance cone and the axis of the shower occurred above ground; that is, showers which passed 'over' the detector before striking the ground. There were 74 such showers, of which 13 were accompanied by a Čerenkov pulse.

Group 2. Showers for which this minimum distance occurred below ground; that is, showers which struck the ground before reaching the detector. There were 78 of these, of which 7 were accompanied by a Čerenkov pulse.

Within the limits of these statistics, then, a shower crossing over the light receiver is twice as likely to give a Čerenkov pulse greater than our detection limit as is a shower which does not do so. This result would lead one to the view that the size of the light pulse detected is likely to be strongly dependent upon the number of particles traversing the acceptance cone of the mirror.

In order to obtain more detailed information on the angular distribution of the Čerenkov light, we next considered only those events where the skew distance between the shower axis and the axis of the acceptance cone was less than 20 m. Of the 87 showers which satisfied this additional requirement, 10 were accompanied by a Čerenkov pulse. Results for these events are presented in Table 3, in which the fraction of showers accompanied by a Čerenkov pulse is given for several ranges of zenith angle. The method of presenting the results is similar to that used in compiling Tables 1 and 2.

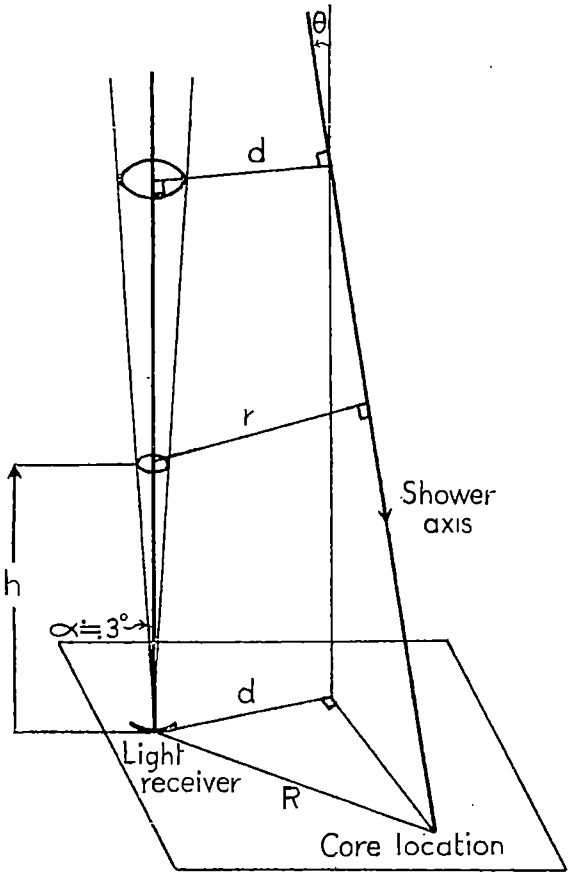

Fig. 2. Schematic diagram of a shower passing 'over' the light receiver

The most significant feature of these results is that the Čerenkov light may be emitted at angles of at least 30° to the shower axis. We thus see that it is not correct to assume that the Čerenkov light is emitted only by particles travelling parallel to the shower axis. As we shall show in the next section, this result is entirely consistent with the theoretically predicted angular distribution of the electrons in a shower. It is also in accord with the numerous photographs of shower electrons in cloud chambers which have been obtained in this laboratory and elsewhere.

The efficacy of the light receiver as a detector possessing a high angular resolution for studies of the anisotropy of air-shower primaries was also investigated, with results shown in Fig. 3. Here are plotted the zenith angle distributions of the 20 showers accompanied by a Čerenkov pulse from the vertical-looking photomultiplier together with the corresponding distribution of all the 157 analysable showers among which the 20 events occurred. It will be seen that for these showers, the cores of which have fallen within a distance of 60 m. from the detector, the requirement that a Čerenkov pulse be recorded has introduced a bias toward vertically incident showers. Half the showers detected by the scintillator array have zenith angles greater than 20°–25°; the corresponding half-angle for the Čerenkov events is 10°. This gain in angular resolution, however, is offset by the accompanying reduction in rate of events recorded.

Table 3. UPPER AND LOWER LIMITS TO THE FRACTION OF SHOWERS ACCOMPANIED BY A ČERENKOV PULSE AS A FUNCTION OF θ, THE ANGLE OF EMISSION RELATIVE TO THE SHOWER AXIS, AND C/N, THE REDUCED SIZE OF THE PULSE

The method of presentation is similar to that used in Table 1

Zenith angle (deg.)	0–10	10–20	20–30	≥ 30
C/N ≥ 10	0·50–0·67 (6)	0·11–0·42 (2)	0·03–0·23 (1)	0·06–0·19 (1)
≥ 20	0·50 (6)	0·05–0·16 (1)	0·03–0·17 (1)	0·06–0·19 (1)
≥ 40	0·17 (2)	0·05 (1)	0·03 (1)	0 (0)
≥ 80	0·08 (1)	0·05 (1)	0·03 (1)	0 (0)
Total number of events	12	19	30	16

It should also be emphasized that this result refers to detected showers the cores of which fall close to the detector. The angular distribution of showers detected using a light receiver alone could be quite different, as discussed further below.

Discussion

The foregoing results indicate quite clearly that the light emitted by the cosmic-ray air shower traversing the atmosphere may be detected at large angles from the shower axis. This fact is not inconsistent with the interpretation that the light is Čerenkov radiation when one considers the angular distribution of the air-shower electrons arising from their Coulomb scattering in the air. Indeed, according to the calculations of Richards and Nordheim[10], the electron angular distribution is expected to be quite broad and for electrons of energy greater than 21 MeV. (the threshold energy for Čerenkov emission in air at normal pressure) the root mean square angle of the electrons relative to the shower axis is 10°.

Although it is not the purpose of the present article to discuss in detail the theoretical interpretation of the Čerenkov light associated with an air shower, it does appear worth while to indicate an approach which should prove useful. For the sake of simplicity we shall ignore the longitudinal develop-

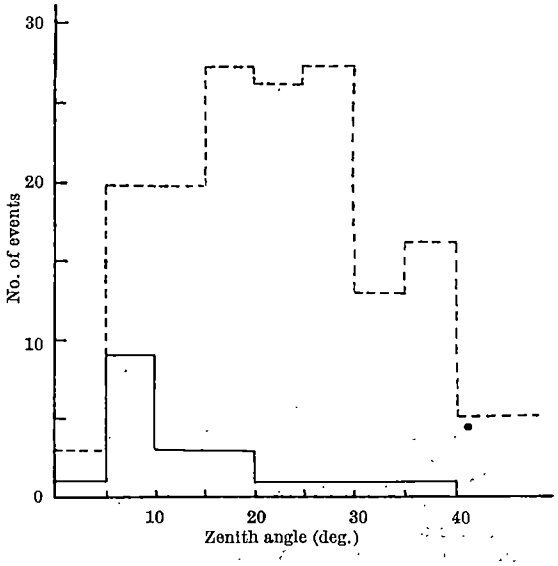

Fig. 3. Zenith angle distributions of 157 showers detected by the scintillator array (dotted line) and of the 20 showers accompanied by a pulse in the vertical-looking light receiver (full line)

ment of the shower. This could be introduced at a later stage when more experimental results are available.

Let us consider the case of a shower of size N, the axis of which is inclined at an angle θ to the axis of the acceptance cone of the receiver. Our notation is as shown in Fig. 2. We first define an average particle density at a particular height h, $\overline{\rho}(h)$. We then define a function $f(\theta,r)d\omega$ which is the fraction of electrons at a distance r from the shower axis which have energies greater than 21 MeV., the threshold for Čerenkov emission at sea-level, and which are travelling at an angle θ to the shower axis in the solid angle $d\omega$.

This angular distribution of the electrons gives rise to an angular distribution, $f'(\theta,r)d\omega$, of the photons. Since the angle of Čerenkov emission (1·3° at sea-level) is much less than the root mean square angle of the electron distribution we may, to a good approximation, replace $f'(\theta,r)$ by $f(\theta,r)$. We may further simplify the problem by replacing $f(\theta,r)$ by $f(\theta,d)$, where d is the skew distance between the shower axis and the axis of the acceptance cone. This appears to be justified since, for the low electron energies considered here, $f(\theta,r)$ will be a slowly varying function of r.

With the above assumptions, the contribution of the electrons at a height h to the number of photons detected by the light receiver is:

$$n(h)dh = k dh\, \overline{\rho}(h)\, f(\theta,d)\, \pi h^2\alpha^2 d\omega = k\overline{\rho}(h)\, f(\theta,d)\, \pi A\alpha^2 dh \text{ photons},$$

where k is the number of photons emitted per particle per unit track length, $d\omega = Ah^{-2}$ is the solid angle presented to the light flux by the mirror of area A and α is the half-angle of the acceptance cone.

If we ignore the variation of k with h, the total number of photons detected will be given by:

$$N = C\int_0^\infty \overline{\rho}(h)\, dh$$

where $C = k\, f(\theta,d)\, A\pi\alpha^2$. That is, the number of photons detected is determined by the integrated particle-density above the detector, and is also determined by the angular distribution of the electrons in the shower.

The experimental results reported in this article are in qualitative agreement with this model. The large fluctuations in the values of C/N as a function of r in Fig. 1 may be ascribed to the fact that the showers detected are not in general vertically incident. The off-centre photomultiplier, which looks out over the scintillator array, detects light pulses in coincidence with air showers detected by the array with greater frequency than does the vertical-looking photomultiplier. The average pulse-height is also greater. Since the majority of showers detected fall with their cores inside the area containing the scintillator array, there is a larger number of shower cores traversing the acceptance cone of the off-centre photomultiplier than is the case for the vertical-looking one.

The distribution of zenith angles of showers the axes of which fall within a skew distance of 20 m. from the axis of the vertical-looking detector is given in Table 3. Knowing the shower structure function, the position where the core has hit the ground and the direction of the shower axis, it is possible to carry out the integration, $\int_0^\infty \overline{\rho}(h)dh$, along the axis of the detector. This has been done approximately for the events of Table 3, and the angular distribution function $f(\theta)$ for the photons, ignoring its possible dependence upon d, has been found to be consistent with the form $f(\theta) \propto \theta^{-0.7}$.

Finally, it is clear from the results shown in Fig. 3 that a vertical-looking light receiver in conjunction with an array detecting air-shower particles will respond to showers falling within a narrower range of zenith angles than would be the case for the detecting array alone. This selection of vertical showers may be produced not only by the forward peaking of the angular distribution of photons about the direction of the shower axis, but also by the larger value of the integrated particle density for a vertical shower.

As pointed out earlier, this selection of near-vertical showers has been shown to apply only to showers the cores of which fall close to the detector. It is quite probable that an air-shower detector consisting of a light receiver alone will respond to showers of quite wide zenith angle distribution, many of the showers detected by it, in fact, traversing the acceptance cone of the receiver at large angles and falling far away from the detector.

Conclusion

From the results reported in this article, it is apparent that in the interpretation of the light pulses associated with the extensive air showers, it is not justifiable to ignore the angular distribution of the air shower particles and the consequent angular distribution of the emitted photons. As a device for the investigation of possible anisotropies in the directions of arrival of the air shower primaries, the Čerenkov detector pointed to the zenith in conjunction with a particle-detecting array will accept showers within an acceptance cone of half-angle appreciably wider than the half-angle of the detector itself. Further investigation is required before one can hope to use the Čerenkov emission from air showers as a means of investigating their longitudinal development.

We wish to acknowledge the facilities made available for this work by Prof. H. Messel and the invaluable support given by the Nuclear Research Foundation. One of us (M. H. B.) has been supported in this work by a grant from General Motors–Holden's, Ltd., and another (C. S. W.) by a grant from the Australian Atomic Energy Commission.

RADIO AIDS TO NAVIGATION

AT a meeting on September 2 of Section G (Engineering) of the British Association in Glasgow, three papers were read on the subject of "Radio Aids to Navigation". The first of these, by Dr. R. L. Smith-Rose, outlined the general problem and dealt with the principles of the determination of position by the use of radio waves. The other two papers, by Dr. B. G. Pressey and Mr. Caradoc Williams, respectively, described the present state of development of radio aids for marine and aeronautical navigation.

From the earliest days of radio the position of a transmitting station has been determined by the technique of radio direction finding. Using a special aerial system, which may be fixed or rotatable, for receiving waves from a transmitter its direction or bearing may be ascertained. With two or more such direction finders the position of the transmitter is determined by the intersection of the bearing lines. In the first half of the twentieth century various direction-finding systems were developed for use on land, ships and aircraft; and, as a result of much scientific research, the accuracy and scope of such systems have been steadily improved. The application of the technique has been very wide and includes not only navigation but also the location of unidentified transmitters and the sources of thunderstorms. A recent extension has involved the tracking of artificial satellites by the signals emitted by it.

An alternative technique places the directional aerial system at the transmitter, and by suitable coding signals, the bearing of this station can be determined from any receiving point. There are several varieties of such directional beacon transmitters, which are in many ways analogous to the ordinary lighthouse from a navigational point of view. In one type the transmitted signal is directed along a particular route, and switched periodically to either side of this direction. By maintaining a position giving equal received signal strengths, a craft can be navigated along the prescribed course. The Consol system provides a variation on this in that a number of courses are specified by an appropriate coding of the transmitted signals, which change systematically over a period of operation, usually half a minute. An observer using an ordinary receiver, and knowing the approximate direction of the transmitter, can make a precise determination of this direction by merely observing the code signals during the operating period.

The development of radar has resulted in the use of an additional technique involving a measurement of the time of transit of the radio waves between sender and receiver, and so of the distance between these stations. The combination of distance and bearing makes it possible to determine position from a single point without the need for cross-bearings as in normal direction finding.

Among the more recent developments are those which are classified under the title of hyperbolic systems. If synchronized pulses are emitted from two stations they will, in general, be received at different times at a remote station on land, at sea or in the air. Using a cathode-ray tube type of presentation, the received pulses can be displayed on a suitable time base, and their relative times of arrival measured with considerable accuracy. The locus of receiving points at which there is a constant time difference is a hyperbola. Thus the observation of the time difference between the pulses locates the receiver on one of a system of hyperbolæ. If a third transmitting station is included in the chain, a second observation defines the position on one of another system of hyperbolæ, and the point of intersection gives the position of the observer. This is the basic principle of the Gee and Loran systems of navigational aid. Similar networks of hyperbolic loci can be established with continuous wave transmitting stations, as in the Decca system. In this case the hyperbolæ are distinguished by a constant phase difference between the signals received from pairs of stations.

Marine Navigation

From the mariner's point of view, the two principal navigational questions to which he requires an answer are, "Where am I?" and "How far am I from danger?" In conditions of poor visibility these questions can only be answered satisfactorily by radio.

Mention has already been made of the oldest type of radio aid, the direction finder, the main use of which is as a ship-borne instrument operating in conjunction with a world-wide beacon network. Developments during the Second World War have given the mariner three new aids: the long-range directional beacon, hyperbolic position-fixing systems and radar. The first, known as Consol, enables a ship to obtain a bearing with the aid of a normal radio receiver by merely listening to the coded signal. The accuracy of the position obtained in this way depends on the distance of the observer from the beacon; up to a range of 1,000 miles from the beacon, it varies from a few miles to about 20 miles. The principle of operation of the hyperbolic position-fixing system is based on the determination of the difference in the distances of the ship from two fixed points by the measurement of the difference in the times of travel of radio waves transmitted from those points to the ship. Two systems of this type are the Decca Navigator, using continuous waves for medium range operation, and Loran, using pulse transmissions for longer range use. Special measuring equipment is necessary at the receiving end in each case, but this has now been developed to the stage of giving the navigator a direct reading of the co-ordinates of his position. Chains of Decca transmitting stations now cover the whole of the British Isles and a large part of Western European waters; there are also four chains in operation in Eastern Canada. The position-fixing accuracy of the system varies from a few tens of yards in favourable areas to a few miles at night at the nominal 240 nautical mile limit of range from the master station. Loran is essentially a long-range system using pulse-modulated signals radiated from pairs of stations spaced 300–600 miles apart. The service range extends to about 700 miles over sea in the daytime, and because of better propagation conditions, to about 1,500 miles at night. The position-fixing accuracy is high, being about 0·5 per cent of the range, that is, 5 nautical miles at 1,000 miles.

Ship-borne radar enables the mariner to 'see' land and certain types of landmarks up to distances of twenty miles or more and, by measuring the distances to identifiable points, he can easily plot his position on a chart. The more important use of radar, however, is to indicate the presence of other shipping and navigational marks, and so give warning of danger and enable narrow channels to be navigated in thick weather. Shore-based radars are now being used for harbour approach surveillance, information on a ship's position being passed to the pilot by radio telephony or, probably in the near future, by televizing the radar screen. Further developments now under consideration include position fixing systems of very wide coverage and devices to increase the amount of information given by the radar.

Special Problems of Aircraft Navigation

Aeronautical navigation involves the planning and control of the movement of aircraft in position and time along defined tracks so as to reach a prescribed destination in safety. The increasing density of air traffic, particularly in the vicinity of the international airports, creates the need for aircraft to operate in closer proximity and with greater regularity during adverse weather conditions. Radio navigation aids now play a vital part in the safe movement of aircraft; and improved accuracy, greater range of operation, up-to-date information and simplified presentation are the primary requirements. Special problems are present in aeronautical navigation because aircraft move at high speed in three dimensions in a medium of low density. The requirements of aeronautical navigation can be conveniently grouped into three classes: (1) long-range navigation beyond about 250 miles when radio signals propagated by reflexion from the ionosphere may be used; (2) short-range navigation up to about 250 miles when surface wave propagated signals may be used in the metric or centimetric wavebands; (3) very short-range precision navigation such as is required for the guidance of aircraft on to an airfield runway, when metric or centimetric wave-length signals may be used.

The methods of navigation may employ the integration of movement with respect to time relative to a fixed point or the movement may be measured within a fixed co-ordinate framework such as a bearing-distance lattice or a hyperbolic lattice. Dead reckoning is an example of the former process, but the errors in the measurement of airspeed and drift angle have necessitated the development of the Doppler system of radio navigation, which measures accurately the ground speed and drift angle, thus enabling an accurate computation of movement to be provided without the support of radio services from the ground. The facility is of great value for navigation over oceans or in undeveloped parts of the world. Since the process involves the integration of movement with time to ascertain a new position, the accuracy of the result is directly related to the quality of the information used and the integration time. The error in the position of one aircraft is unrelated to the error in position of another aircraft which may be in proximity to it, and under these conditions the measures necessary to prevent collision are obscure. The ideal system of navigation will provide increasing accuracy as the points of danger are approached.

These limitations of the processes employing time integration are the primary reason for the use of systems which lay down a fixed co-ordinate framework in which the aircraft move. If this co-ordinate framework is in use by all aircraft within its coverage, the relative errors in the positions of aircraft are highly correlated and the degree of correlation increases as the craft approach one another.

The simplest form of aeronautical navigation is by use of an airborne direction finder called the automatic radio compass, which provides fixing or homing information with respect to simple low-power non-directional ground beacons or to broadcast stations. By present needs, the aircraft radio compass is a rather inaccurate device because of the small physical size of the loop aerial, and the difficult siting conditions for the loop on the aircraft fuselage. Furthermore, substantial errors can occur at night resulting from signals reflected by the ionosphere which are not plane polarized.

For long-range navigation, low-frequency continuous wave or pulse-modulated signals may be used. These are radiated from widely separated stations which are time interlocked to define a hyperbolic co-ordinate system. Groups of three or more stations form a chain, from which a position can be derived from two or more intersecting hyperbolic position lines. An example of this system is Dectra, which uses continuous wave signals in the 70 kc./s. band to provide track and position along a number of airways which may be 2,000 miles or more in length. It makes use of both ground and ionospheric wave reflected signals depending upon the distance from the stations. The Loran system already referred to has also been widely used for aeronautical purposes.

For short-range navigation, both distance-bearing systems and hyperbolic systems are used. The V.O.R. system provides the means of flying along any radial track by receiving modulated very high frequency signals from a ground beacon which shows the direction of the beacon on a bearing type indicator. A pulse-modulated distance-measuring equipment called D.M.E. can be used in conjunction with it, in which pulse interrogations originating from an aircraft trigger a ground beacon which gives pulse replies, the round trip time being used to indicate distance on the scale of a meter. The problems of the equipment accommodation and the location of the separate aerials in an aircraft necessitated an effort to integrate the bearing and distance services together. This has been achieved in a pulse-modulated system called TACAN, which operates in the 1,000 Mc./s band. As in D.M.E. the pulse signals are initiated in the aircraft and replies are given from a ground beacon which indicates to the pilot the distance of the aircraft from the beacon. The ground-to-air transmissions from the beacon are space modulated to carry bearing information, which is presented on a circular scale bearing indicator, the distance from the beacon being visible in a small window in the indicator dial.

An alternative short-range hyperbolic navigation is provided by the Decca Navigator. By the use of low frequencies of the order of 100 kc./s. and spacing the master and slave stations by 50–100 miles apart, a hyperbolic system of high accuracy is provided. For use in aircraft where instantaneous position indication is required a display is used which shows automatically the movements of the aircraft upon a map.

Some kinds of navigation require great precision over a limited area of coverage, as, for example, the landing of aircraft during bad visibility. These movements create hazards where the points of danger are imminent, and the navigation aids must provide immediate and accurate information. At present, guidance can be given in azimuth and descent by using a precision radar located on the airfield. A ground controller gives a verbal commentary of the approach situation to the pilot on the very high frequency communication channel. He gives the pilot courses to steer, rate of descent and other information during the approach to the airfield until the pilot is within visual distance of the runway.

An alternative form of airfield guidance is by the instrument landing system (I.L.S.), which sets up radio beams to define the lateral and descent path of the aircraft to the airfield runway. The aircraft displacement from the defined track is indicated to the pilot on a meter which has two needles pivoted at right angles. The intersection of the needles with respect to the centre of the dial indicates the correction which the pilot has to make to restore his position on the beam. With large aircraft the practice is being introduced to link these guidance signals to the automatic pilot, so that the descent to the airfield is made under automatic flight control, with the pilot acting as a supervisory monitor to the approach. When he sees the airfield landing lights he takes over full manual control of the aircraft until it is at rest on the runway. The need for complete reliability of the control equipment at this crucial stage is a matter of paramount importance.

MODERN PROBLEMS IN FRICTION AND LUBRICATION

A JOINT meeting of Sections A (Physics) and G (Engineering), under the chairmanship of Prof. J. Small, was held on September 2 at the British Association meeting in Glasgow. In opening the session Dr. F. P. Bowden (University of Cambridge) discussed some problems involved in travelling at speeds of the order of 2,000 m.p.h. The first part of his paper described work in collaboration with Dr. E. Freitag on sliding friction between solid surfaces at these enormous speeds. Elegant experiments using apparatus based on Prof. Beams's magnetic ultracentrifuge had made it possible to study this in the laboratory. At slow speeds of sliding the friction between clean metals is very high, and heavy seizure and surface damage occur. As the speed is increased, however, the friction falls and at sliding speeds of 2,000 m.p.h. it is very low indeed—of the same order as for lubricated surfaces. It would seem that at these speeds the frictional heating which is generated at the sliding interface is sufficient to melt a thin surface layer of the metal; this acts as a lubricant and enables the surfaces to slide easily with low friction and little damage. As a result it may be easier to slide metals over one another at 2,000 m.p.h. than at normal speeds.

Unfortunately not all metals behave in this way. With antimony, for example, surface melting and low friction occur at speeds below 800 m.p.h., but at speeds exceeding this the metal becomes brittle and disintegrates into a fine dust.

The second part of Dr. Bowden's paper described work done in collaboration with Mr. J. H. Brunton on the way in which solids may be damaged if they are hit by rain-drops travelling at speeds of 2,000 m.p.h. A demonstration was given of shooting small cylinders of water (corresponding in volume to a rather large rain-drop) at various surfaces at speeds of this order, the main part of the apparatus being a simple airgun modified to produce the required result. With even the hardest metals the pressures developed at the region of impact are sufficient to produce plastic flow and a saucer-shaped crater is formed in it. With plastics, glasses and ceramics which are strong in compression but weak in tension the behaviour is, however, quite different. The region at the edge of the impact area is subjected to large tensile forces and circular ring cracks are formed. These cracks penetrate beneath the surface and a few successive impacts can cause a large piece of the material to fall out.

Another source of damage which can be even more serious arises from the reflexion of the shock-wave (generated by the impact) in the solid. This travels back as a tensile stress and can detach large fragments of solid from the rear face of the solid. In conclusion Dr. Bowden emphasized that "if we wish to go hurtling around the Earth at a few thousand miles per hour we must learn more about the way in which solids slide, bend and break at very high speeds".

The second contribution, on "Rolling, Skidding and Sliding", was given by Dr. D. Tabor (University of Cambridge). He pointed out that in ordinary sliding the friction was due to two main factors: the shearing of interfacial junctions and the grooving or deformation of the softer surface by asperites on the harder. For most sliding systems the second factor was of minor importance, but there were two situations where it tended to dominate the frictional behaviour. The first was in pure rolling. Even if junctions were formed, the work required to peel the surfaces apart was immensely smaller than the force required to shear these junctions in sliding. The main factor now remaining was the work of deformation, and this could be appreciable even if the surfaces are deformed only elastically. The loss of energy is due to elastic hysteresis in the solids and a demonstration was provided showing that the rolling friction on a rubber of low hysteresis loss was considerably less than on a rubber of high hysteresis loss.

The second situation is observed in pure sliding if the surfaces are so well lubricated that the shearing of the interfacial lubricant film requires only a very small force. In such a case the deformation of the underlying surface may again dominate the frictional behaviour. Thus for hard sliders rubbing on well-lubricated rubber the friction is determined primarily by deformation losses in the rubber itself. A demonstration showed that when rubber slides over a rough, well-lubricated surface the sliding friction is greatly increased if a rubber of low resilience or high hysteresis loss is used. Dr. Tabor concluded by suggesting that a combination of tyre-treads of non-resilient rubber and roadways with a 'knobbly' surface could appreciably reduce the risk of skidding on wet or slippery roadways.

The third paper, on "Lubrication in the Nuclear Age", was given by Dr. C. G. Williams (Shell Research, Ltd.) and dealt with those special mechanisms in nuclear power stations which require lubrication and are exposed to heavy irradiation. Most lubricants deteriorate as a result of irradiation, the deterioration being determined by the energy of the irradiation and not by its type (neutrons, electrons, gamma-rays).

Irradiation energy leads to a break-up of the lubricant molecule with subsequent polymerization and the formation of gumlike or even solid products. Non-petroleum synthetic materials such as silicones do not appear to be very resistant to irradiation; ordinary hydrocarbon oils are somewhat better but the compounds most capable of resisting the harmful effects of irradiation are aromatic hydrocarbons. Apparently the aromatic molecule can absorb energy and then emit it as heat or light without decomposing.

Conventional greases are particularly susceptible to irradiation. They generally consist of a network of soap fibres which encloses the oil globules. Irradiation appears to fragment the fibres so that separation of the oil takes place. A new type of grease has now been evolved in which the soap fibres are replaced by minute clay particles. These particles are strongly attracted to one another and are unaffected by radiation. The grease structure is thus stable, and by using an oil containing a large fraction of aromatic materials a grease is obtained which stands up to irradiation surprisingly well. Dr. Williams's lecture concluded with a short film which illustrated the main themes of his paper.

The fourth paper, by Dr. F. T. Barwell (Mechanical Engineering Research Laboratory (D.S.I.R.), Thorntonhall), dealt with "Newer Aspects of Hydrodynamic Lubrication". He provided a simple direct demonstration of Beauchamp Tower's famous experiment of 1885 which showed that the lubricant between a journal and a bearing developed high hydrostatic pressures capable of supporting the load on the journal. It was this work which led to Osborne Reynolds' classical theory of hydrodynamic lubrication. Although Reynolds' work was of immense importance and had been greatly extended by the use of modern electronic computers there were at least four deficiencies which recent work has revealed. First, Reynolds assumed that the oil film cannot support negative pressures whereas experiments now show that negative pressures in the oil film can exist. Secondly, the oil film is not continuous but breaks up into fibrils in the regions of negative pressure. Thirdly, Reynolds assumed that the viscosity was constant whereas modern work shows that viscous heating reduces the viscosity, while high pressures increase it. Finally, because of thermal effects and elastic flexing of the shaft, bearings run more satisfactorily at high speeds if they are narrower than the classical theory suggests.

Two other problems of current importance arise if the load is not constant in a uniform direction. If the load rotates it can be shown that a critical condition exists when the frequency of the applied load is half that of the shaft. The load-bearing capacity of the bearing becomes vanishingly small and there is very great danger of bearing-failure. The second type of instability which has attracted considerable attention in recent years is that associated with shaft vibration or whirl, and several procedures have been developed for minimizing its more serious features.

Finally, Dr. Barwell referred to the possibility of using air as a hydrodynamic lubricant and demonstrated a commercial electric motor which, with only slight modifications, operated very successfully on air bearings.

The last paper, by Dr. J. F. Archard and W. Hirst (Associated Electrical Industries, Aldermaston), on "The Wear of Metals", was presented by Dr. Archard. The results of many hundreds of wear experiments have led to four relatively simple rules of wear. The first general rule is that at the start of a wear experiment the rate of wear changes as the surface conditions change, but eventually these become stabilized and steady wear conditions obtain. Secondly, under steady conditions the wear rate becomes constant and is roughly independent of the area of the rubbing surfaces. Thirdly, for many materials the steady-state rate of wear is almost proportional to the load. Finally, with metal surfaces there are two main types of wear, 'mild wear' below a critical load and 'severe wear' above it. Under conditions of mild wear, the worn fragments are usually very small, perhaps only a few hundred angstroms across, whereas in severe wear large lumps of metal are torn out of the surfaces.

Although in certain cases a wear fragment may be produced when an asperity on one body shears through the surface layers of the other this is not generally the case. Elegant experiments using radioactive transfer techniques show that in many cases one metal transfers itself as a thin film on to the other as a result of adhesion and shearing of interfacial junctions. The transferred fragments then gradually coalesce and are fatigued by repeated rubbing until they break away from the surface and appear as wear fragments. The exposed surface then becomes covered with a new layer of transferred material and the process continues in this way. The results show that the wear process is often very complex indeed. Finally, Dr. Archard discussed the mechanism of wear in terms of a model involving asperity encounters in which all the encounters contributed to the friction but only a small fraction of the encounters could lead to wear. This model was consistent with the enormous range of wear-rates observed for different materials. Thus although the coefficient of friction for the most diverse solids does not vary by more than a factor of three or four the wear-rates may vary by a factor of more than 100,000. D. Tabor

THE INSTITUTE OF METALS

Although there has been a non-ferrous metallurgical industry in Britain from time immemorial, it was not until 1908 that any organization was available for the general dissemination of knowledge and research in this field. The Iron and Steel Institute had performed such a function for its own branch of metallurgy since 1869, and mining and the extraction of metals, chiefly non-ferrous, were covered by the publications of the Institution of Mining and Metallurgy.

It may well be that the delay in the formation of a body such as the Institute of Metals, which celebrates its golden jubilee this year, was in large measure due to the secrecy which obtained. From the earliest days existing knowledge had been passed on from master to apprentice, and at a later age the guilds had, as part of their functions, to ensure that the apprentice received an adequate training and gave satisfactory proofs of proficiency in his trade before passing on to higher status. It was inevitable in such circumstances that existing knowledge should be restricted to those in the immediate circle, and a similar secrecy existed, though to a diminishing degree, even down to very recent times. Even after the formation of the Institute, successive presidents, year after year, had in the earlier stages of its life to plead for more papers of a 'practical' nature.

It did, therefore, represent a much more liberal outlook when a preliminary meeting, mainly of those concerned in the copper and brass industries, met in Manchester in 1908 to consider the formation of an Institute much on the lines of the existing ones, but for the non-ferrous metals. At a subsequent meeting in London it was resolved that such an Institute, to be called the Institute of Metals, be formed, and the new body held its first meeting in Birmingham in that year.

This Institute has performed many useful functions, but it may be that none of these will ultimately prove to have been of greater industrial value than its general dissemination of experience and new knowledge, not only in Britain but also throughout the world. In its fifty years of life there has been a quite revolutionary change in this respect, and such interchange of information, even between competing organizations, is now the rule rather than the exception. Perhaps there is no more concrete evidence of this fact than the success with which the Institute, largely through its Metallurgical Engineering Committee, has been able to organize symposia, such as those on "Internal Stresses in Metals and Alloys" or "The Metallurgical Aspects of the Hot (and later Cold) Working of Non-Ferrous Metals and Alloys". In those symposia an enormous amount of practical, factual material of the highest importance to industry was published and very frankly discussed.

So far it is the directly practical aspect of the Institute's activities and influence which has been considered, but there is another, and no less important, side to its work. Until its formation, publication of scientific research on the non-ferrous metals was dispersed throughout a wide field of publications. Now, for the first time, a single focus was available in which the vast majority of work done in Britain, and to some extent abroad, was collected. From its very inception the standard of the papers which the Institute has published has been high, and never more so than to-day, and its *Journal* is rightly regarded throughout the world as a scientific publication second to none in the metallurgical field. How much, for example, the development of age-hardening alloys owes to the papers which the Institute of Metals has published cannot, of course, be adequately assessed, but there is no doubt that in this, and in many similar fields, the work which it has published has played an outstanding part.

At one time it was directly concerned with the experimental investigation of corrosion, particularly of condenser tubes, and the success with which this was carried out may be gauged from a testimony of Sir Winston Churchill who, in introducing the Navy estimates for 1940, said: " 'Under the adverse circumstances', to quote a hero's phrase, our ships great and small have been at sea more continually than was ever done or dreamed of in any previous war since the introduction of steam. Their steaming capacity and the trustworthiness of their machinery is marvellous to me, because the last time I was here one always expected a regular stream of lame ducks from the fleets to the dockyards with what was called 'condenseritis', or heated bearings, or other mechanical defects. But now they seem to steam on for ever".

It was realized, however, that the active pursuit of research was not the true function of such an institute, but its single excursion into such a field was highly successful.

To one who, like the present writer, entered metallurgy before the era of the modern—and perhaps he may be allowed to say hypothetical—aspects of metallurgical research were even thought of, it is not easy to assess their ultimate importance in connexion with metallurgical science and technology. When, however, the vast amount of published work which has been coming out from research institutions of all kinds in an ever-increasing flood has been brought together in more concrete terms, a new attitude may well initiate a completely new point of view to producers and users alike, and if this should prove to be the case, those workers whose results have appeared in the Institute's *Journal* and, be it said, all those responsible for the production of this most excellent publication will have played a yeoman part.

It would be quite improper in such a consideration of the Institute's activities to omit mention of the excellent abstracts, which have formed an essential part of its publications from the first. These, in their scope and presentation, are recognized as being inferior to none in the metallurgical or, probably, in any other field.

Another activity of the Institute is represented by its 'May' and 'Autumn' Lectures. The former (generally delivered in March) is a scientific oration not of direct industrial significance but at the same time not without its indirect bearing. The Institute has been particularly fortunate in the men of highest reputation who have accepted its invitation to deliver these lectures. Sir William and Sir Lawrence Bragg, Sir J. J. Thomson, Lord Rutherford, Sir Henry Miers, Sir Willis Jackson are names which come immediately to mind. Through these lectures the members are introduced to fields of knowledge which, though not immediately applicable, may at any time become so. The Autumn Lecture, on the other hand, is concerned with some matter of a more practical nature, often of special importance to the district in which the meeting is held.

In this, as in the case of any similar institute, its growth and influence are directly due to the efforts of those men who work for, and direct the progress of, the organization. A mere list of names of such men would, in the case of the Institute of Metals, be quite formidable, and it is no easy task to pick out even a few whose influence has been of outstanding value. Two of these, however, must clearly be Mr. G. Shaw-Scott, the first full-time secretary of the Institute, who acted in that capacity until his retirement in 1944, and his successor, the present secretary, Lt.-Col. S. C. Guillan. It has been the policy of the Institute from the beginning to choose its president and council in more or less equal numbers from the producer, the user and the scientist, and in all these groups men of the highest attainments have served. The first president of the Institute, Sir William White, had been the director of naval construction and, as consultant to the Cunard Steamship Co., was largely responsible for the construction of the *Mauretania*. Later presidents, such as Sir Gerard Muntz, Prof. Gowland, Sir Henry Oram (engineer-in-chief of the Fleet), Dr. Rosenhain (head of the Metallurgy Department of the National Physical Laboratory), Sir George Beilby, Sir John Dewrance, Dr. Desch, Dr. Seligman, are merely typical of those to whom the Institute owes so deep a debt.

This review has not been able to touch on other important aspects of the Institute's work, its publications, for example, other than those of new research. Among these, the successive editions of Prof. W. Hume-Rothery's contribution to our knowledge of atomic theory as applied to alloy systems are outstanding.

It is not surprising, therefore, that, after a comparatively slow start, the membership of this Institute has grown progressively until it now exceeds five thousand, the members being drawn from every country in the world in which a metallurgical industry exists.

DISTRIBUTION OF PROFLAVIN-INDUCED MUTATIONS IN THE GENETIC FINE STRUCTURE

By DR. S. BRENNER, PROF. S. BENZER* and MRS. L. BARNETT

Medical Research Council Unit for Molecular Biology, Cavendish Laboratory, Cambridge

THE mutagenic action of 5-bromouracil is highly specific, inducing mutations at points differing from those at which spontaneous mutations most frequently occur. This was demonstrated by Benzer and Freese[1] using genetic mapping techniques of high resolution as applied to the r_{II} genetic region of bacteriophage *T*4. Such specificity suggests the possibility of using various mutagenic substances to probe the chemical nature of the genetic fine structure.

We have investigated mutation in the same genetic material induced by proflavin which had been shown by De Mars[2] to be mutagenic in phage. Proflavin is known to interact with deoxyribonucleic acid but, unlike 5-bromouracil, does not appear to become incorporated. Comparison of the distribution of r_{II} mutations induced by proflavin and by 5-bromouracil shows that these two mutagens act on completely different groups of sites in the genetic structure.

Production of Mutants

Proflavin, although not interfering with synthesis of deoxyribonucleic acid in phage-infected cells, inhibits the maturation of phage progeny particles[3,4]. In order to obtain an infective yield, therefore, the proflavin must be removed before the onset of lysis, thereby limiting the time during which it can be allowed to act as a mutagen. In the present work, we have employed a modified technique which in effect permits the separation in time of genetic replication from the maturation process. If chloramphenicol is added ten minutes after infection, protein synthesis is arrested but phage deoxyribonucleic acid replicas continue to be produced[5]. Brenner and Smith[6] have shown that mutations can be induced in the deoxyribonucleic acid formed under these conditions. When the chloramphenicol is removed, mature phage particles begin to form and cell lysis proceeds. We have made use of this finding to maximize the induction of mutation with proflavin.

A stock of *T*4*Br*+ with a low proportion of spontaneous *r* mutants was selected from among several stocks grown from small inocula. This stock contained one *r* plaque among 19,000 plaques examined. *E. coli*, strain *B*, was grown in glucose-salts medium to 2 × 10^8 cells/ml. To 10 ml. of this culture was added proflavin to a final concentration of 4 μgm./ml., and 2 × 10^8 particles of *T*4. After ten minutes of incubation at 37° C., 20 μgm./ml. chloramphenicol was added and incubation continued for one hour. During this period, samples were removed at fifteen-minute intervals, diluted five thousand-fold in glucose–salts medium, titrated for infective centres and incubated for one hour. These experiments showed that during chloramphenicol growth, the infective centres decreased by a factor of four, the average burst size decreased from 200 to 20, and the frequency of *r* mutants among the progeny rose from 0·1 to 0·5 per cent.

Mutants were isolated in two ways:

(1) After one hour in chloramphenicol, the culture was diluted in glucose–salts medium to contain 500 infected cells per ml. and 0·2 ml. dispensed into each of many tubes, which were then incubated for one hour. The contents of each tube were plated on *E. coli B* and 42 independent *r* mutants were isolated, picking one *r* mutant from each tube. The proportion of *r* mutants among the progeny was 0·5 per cent, which represents an increase of about 30-fold over the spontaneous mutation-rate (that is, without proflavin).

(2) After one hour in chloramphenicol, aliquots of the culture were diluted and plated immediately on *E. coli B*. The plaques on these plates arose from infected cells, and the presence of an *r* mutant in the burst from a cell could be noted by the mottled appearance of the plaque. 48 independent *r* mutants were isolated from separate mottled plaques.

In the genetic analysis which follows, there was no apparent difference in the mutants isolated by these two procedures.

Genetic Mapping of the Mutants

The procedure for mapping the proflavin-induced mutations within the r_{II} region of phage *T*4 was the same as that previously described by Benzer and Freese[1]. In brief, the steps were: (1) the r_{II} mutants were chosen by their defective growth in *E. coli*, strain *K*; (2) the mutations were assigned to segments of the region by crossing them with a special set of r_{II} mutants which define these segments; (3) the mutants in a given segment were then crossed

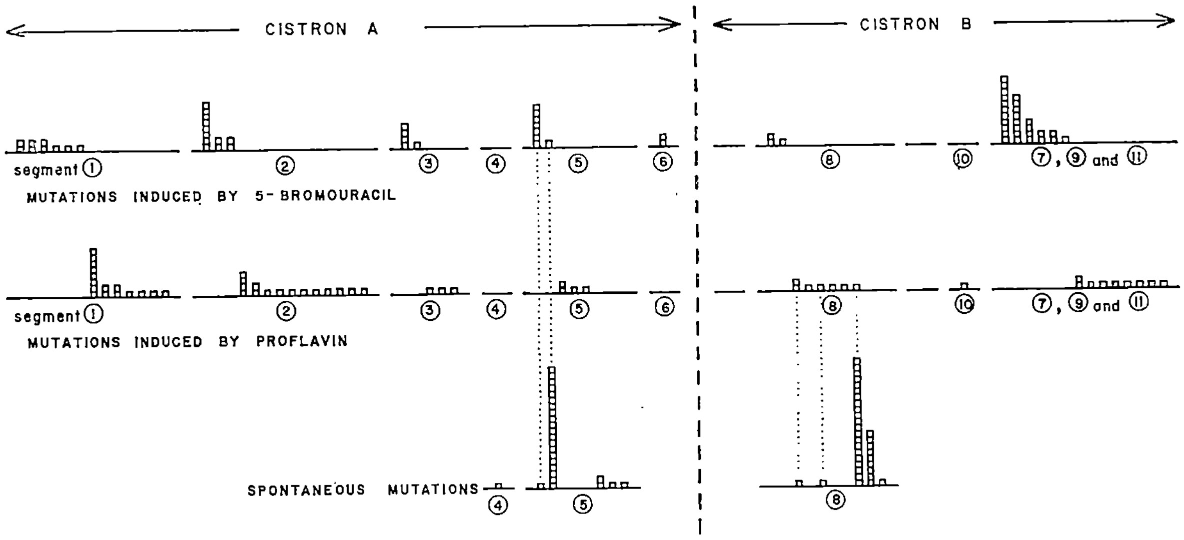

Fig. 1. Genetic maps showing the locations of mutation in the r_{II} region of phage *T4*. Each mutation is represented by a box placed in the proper segment of the map. The relative order of segments 1, 2, 3, 4, 5, 6, 8 and 10 is established, but segments 7, 9 and 11 are lumped together and considered as one segment. Within each segment the mutations are arranged only according to whether they fall at the same or at different sites, without regard to their relative positions in the genetic structure. The comparison of spontaneous mutants with the two sets of induced ones is only given for segments 4, 5, 8. (The overall mutation rate is different in each case. The occurrence at a given location of one mutation in the bromouracil set corresponds to roughly 10^3 times higher mutability at that spot than one occurring in the spontaneous set. In the case of proflavin this factor is of the order of 10^2)

with each other to determine which mutations have different locations. The mutations induced by proflavin were then compared with those induced by 5-bromouracil, by crossing a mutant from each of the proflavin sites in a given segment with one from each 5-bromouracil site in the same segment.

Results

Of the 90 proflavin-induced r mutants, 58 were defective in growth on strain *K*, and were therefore assigned to the r_{II} group. 3 of these r_{II} mutants were not definitely mapped, one had a high reversion-rate and two were complex (possibly double mutants) and require further investigation.

The reversion-rates of proflavin-induced r_{II} mutants are generally quite low. Of the 58 mutants all except two were sufficiently stable that stocks of them contained less than the order of 10^{-6} revertants. In this respect, mutants induced by proflavin resemble those induced by 5-bromouracil. By contrast, many spontaneous mutants have high reversion-rates.

The results of mapping the 55 r_{II} mutants induced by proflavin are shown in Fig. 1. In this map, mutations are indicated as being only at the same or at different sites and the relative locations of mutations within a segment have not been determined. To facilitate the comparison of spectra with the bromouracil spectrum found by Benzer and Freese the sites in each segment have been plotted in order of decreasing mutability for each mutagen.

The comparison of the induced spectra with that of spontaneously arising r_{II} mutants has been made for segments 4, 5 and 8, which contain the major spontaneous 'hot spots'. As is evident from the figure, these sites do not appear as 'hot spots' in either of the induced spectra. Therefore, proflavin like bromouracil does not simply raise the overall mutation-rate but acts at specific, though numerous, sites.

A few of the sites in the induced spectra coincide with the sites of spontaneous mutation. Some of these coincidences can be ascribed to a background of spontaneous mutants to be expected in the induced sets, since the mutagens raised the overall mutation-rate only by a factor of 30 in the case of proflavin and 100 in bromouracil. Other coincidences may represent true increases of mutation-rate produced by the mutagen at a spontaneous site.

A remarkable feature in the comparison of the bromouracil- and proflavin-induced mutation is that each mutagen appears to act on a set of sites quite distinct from the other. Were the spectra similar, about half the mutations induced by proflavin should have occurred at sites already induced in the bromouracil spectrum. The absence of any coincidences is therefore highly significant.

It is interesting also to examine the distribution of recurrences within each spectrum, as shown in Fig. 2. In the case of proflavin, the existence of single occurrences at many sites implies that there remain additional sites at which no occurrence has yet been observed. An estimate of the number of such sites may be made as follows: assuming a set of sites of equal mutability, the number of occurrences at each of these sites should follow a Poisson distribution, so that the number of sites with zero occurrence can be computed from the ratio of the number with two-fold to the number with single occurrences. The data would then indicate that there exist 96 proflavin sites not yet indicated on the map. This is, of course, a minimum estimate, since there may exist as well many additional sites of lower mutability. Clearly, therefore, the proflavin map shown in Fig. 1 is far from exhaustive.

The distribution for bromouracil appears bimodal. There are four spots of very high (and possibly identical) mutability; it is very unlikely that any additional sites of comparable mutability could have failed to be indicated. Even among the less mutable sites, the ratio of two-fold to single occurrences suggests that only a few comparable sites are not yet indicated.

Although the mutagenic effects of proflavin have been studied in many organisms (bacteria[7], yeasts[8],

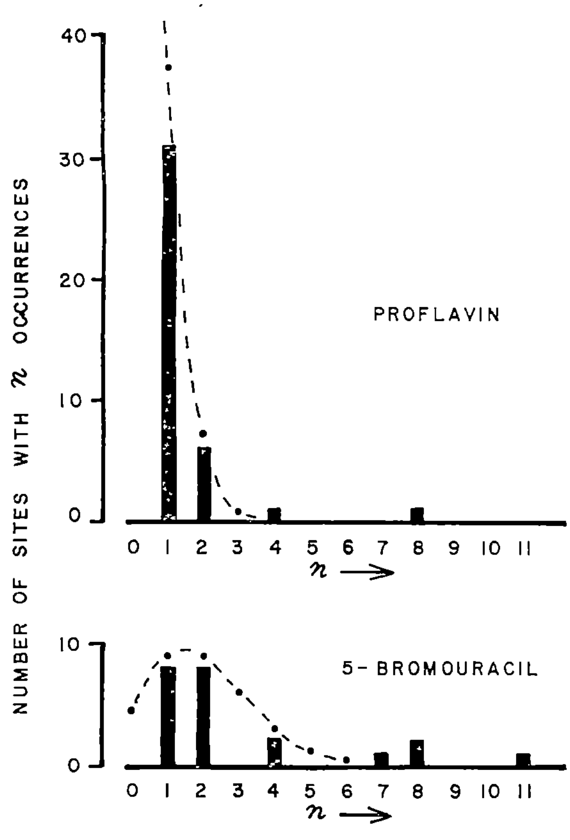

Fig. 2. Distribution of mutation over the various sites induced by proflavin and bromouracil. The dotted line in each case shows the Poisson distribution computed from the ratio of sites with two-fold occurrence to sites with single occurrences

bacteriophage[2] and polio virus[9]) the mechanism of its action is unknown. Unlike bromouracil, proflavin does not appear to be incorporated into deoxyribonucleic acid. Astrachan and Volkin[10] compared bacteriophage deoxyribonucleic acid with that produced in the presence of proflavin. They found some differences between heat-degraded samples, but the significance of this is unclear. Deoxyribonuclease digests, however, were similar, indicating that proflavin did not produce extensive modifications of nucleotide composition or sequences. Proflavin and related acridine dyes are known to form complexes with nucleic acids[11]. Steiner and Beers[12] showed that the combination between polyadenylic acid and acridine orange (the tetramethyl derivative of proflavin) involves interaction between the dye and the adenine ring. The dye does not interact in this way with deoxyribonucleic acid, presumably because adenine is rendered unavailable by hydrogen bonding with thymine nucleotides. Instead, it combines with the phosphate groups[13]. During replication, however, deoxyribonucleic acid may have a configuration in which the nucleotide residues become available to the acridine dye. Such interaction may then be responsible for producing mutations.

The contrast between the three mutational spectra underlines the complexity of the genetic fine structure. A cistron evidently is composed of a large number of mutable elements of several kinds. It should be fascinating to relate these local details to the precise chemical constitution of the genetic structure, but without further knowledge of the chemical mechanisms of mutagenesis this is not yet feasible.

UTOPIAN EDUCATION

TO commemorate the period when that great nineteenth-century educationist, C. J. Vaughan, was vicar of Doncaster—later he became Master of the Temple and, then, Dean of Llandaff—an annual lecture is delivered in Doncaster Grammar School, which itself owes so much to Vaughan's interest and influence.

The lecturer in 1958 was Prof. W. H. G. Armytage, professor of education in the University of Sheffield, who examined the Utopist tradition in English education*. The name 'Utopians' has been invested with associations of eccentricity and futility. Marx and Engels began the process when they described the Utopians as "fanatical and superstitious" and "pedants", and as "promoters of duodecimo editions of the new Jerusalem". Sidney Webb accused them of having too little faith in human nature, and confessed that they seemed to him to be "throwing up the sponge in despair". Arnold Toynbee allows that "the utmost to which all Utopians aspire is to arrest a downward movement".

The historical Jesus, when talking of the Kingdom of Heaven, gave the Utopians their charter. For, as they read it, the Kingdom was not to be a Church Militant, but a real community bound by love and not by law. Not until the time of Sir Thomas More did the Utopian get his programme. For More's "Utopia" virtually idealized a community. More also brought physical science within the compass of the community.

This was an important accretion to the tradition. Science began to be regarded, and especially by Francis Bacon, as the instrument by which the evil consequent upon the Fall could be expunged. Bacon insisted that material progress could not bring happiness without love, and love was ineffective without power. This power lay through inventions, and, as Bacon looked at history, he saw each invention as a guarantee of truth and the effectiveness of science. Like St. Paul, Bacon believed that philosophy should produce works. He disliked classical philosophy because it committed the sin of trying to conjure the knowledge of Nature out of the mind rather than out of Nature itself.

---

* The Utopist Tradition in English Education. By Prof. W. H. G. Armytage. (Sixth Vaughan Memorial Lecture.) Pp. 16. (Doncaster: Doncaster Grammar School, 1958.) 1*s*. 3*d*.

Bacon is a modern prophet. He inspired not only J. V. Andreae's "Reipublicae Christianopolitanae Descriptio" (1619) and the Jesuit Campanella's "Civitas Solis" (1623), but also the founding of the Royal Society in England.

The Utopians were building up a tradition of their own. Andreae had a great influence in England. Among the leaders of a group which worked to establish a *societas christiana* were Samuel Hartlib, John Dury and John Amos Comenius. They believed that it was the essential preliminary of the Christian society that a system of universal schools should come into operation to teach all men all things. Hartlib worked to establish a university in London in which there should be taught the scientific principles of trades, like glass-working and metallurgy. Comenius, unfortunately, could not go ahead with his scheme for establishing a college at Chelsea. But the idea persisted, in the Royal Society, and comes down to us virtually undimmed in intensity. Perhaps its best twentieth-century exponent was H. G. Wells, who acted as an evangelist for science.

Much of modern Utopist thought can be discovered in the literary genre known as science fiction. There is another and more important aspect of Utopist endeavour which is almost entirely forgotten. This is the story of those who tried to form communities. The Quakers are pre-eminently communitarian in their approach to religion and education. It was a quartet of Quakers who backed the second great English Utopian, Robert Owen, when he purchased his father-in-law's factory in 1813 to carry out his experiment on the formation of character at New Lanark. The established Church took umbrage at the environmentalist nature of his creed. There was, however, one member of the Established Church who believed in Owen's idea of the regenerative power of community life. This was John Minter Morgan, who is a good embodiment of the Utopist mentality. He was a philanthropist with a private income, and in 1826 he published a book called "The Revolt of the Bees". It was the story of a hive that went through five revolutions, from "noble savagery", through "pastoral occupations", "farming" and "industry", to a fifth revolution pioneered by "the wise bee" (Owen). After this fifth revolution all benefited from a redistribution of the fruits of wealth and knowledge. The "practical and durable form" was for communities to be built surrounded by parks and gardens, to house 1,000 families. The interesting point about Morgan's suggestion was that those who did not live in communities would be able to use the churches as community centres. He envisaged the churches being open on work-days and evenings for lectures and general community activities. This plan was put into operation in Sheffield two years ago with the establishment of St. Mary's Community Centre at Bramall Lane. Morgan, like Owen, envisaged education as the instrument whereby the general level of the population could be raised. In 1833 he urged the authorities of the newly founded University of London to establish a chair of education; this is the first direct proposal for such a chair in England.

In the 1840's Morgan formed a group to secure the establishment of what he called a self-supporting village, but which to-day would be called a satellite town. Among his supporters were the Rev. Francis Close at Cheltenham, the Vice-Chancellor of Oxford, and William F. Cowper.

Another convert was a former member of parliament for Sheffield, James Silk Buckingham. Buckingham spoke most warmly on behalf of Morgan's scheme for an experimental community, and suggested that one might be started at Hounslow Heath or Salisbury Plain. Buckingham came out three years later with his own proposal for a community. This proposal was the first concrete and complete plan for a garden city; it contains a number of uncanny prognoses of future developments. The centre of the town was to be a large green park with the main public buildings grouped around it. Houses were to be in broad avenues in square belts around the civic centre. Workers' dwellings were to be in houses on the outside frontage of the town, near the green belt. A liberal intermixture of open spaces and parks was suggested to relieve the drabness of these. Houses were to be graded according to the size of the families and their economic circumstances. Children were to stay at school until they were fifteen years of age; medical service was to be free, with doctors paid by the community to prevent disease. Civic restaurants were to be established to feed the inhabitants. It was Buckingham's plan which inspired Ebenezer Howard, founder of the Garden Cities Association.

In spite of hostile reception, the Garden Cities Association was formed in 1899. This Association was responsible for the establishment of the first garden city at Letchworth in 1903. The Garden Cities Association helped in the development of garden suburbs at Hampstead, Warrington, Hull, Bristol, Cardiff, Manchester, Rosyth, Liverpool, Ruislip, Bolton, Rochdale and Woodlands, near Doncaster.

The climate of opinion which nourished the Garden Cities Association also produced the Fellowship of the New Life, an informal group founded in Chelsea in 1882 by Thomas Davidson; members of the society were required to lead a higher life. It was a difference of opinion over the formation of a community in England which led some of the Fellowship to separate from the parent body and form the Fabian Society. The secretary of the Fellowship was Ramsay MacDonald, and its main activities were promoting not so much experimental communities as experimental schools. The first Fellowship school was founded at Abbotsholme in Staffordshire. "All schools," insisted the Fellowship's journal, *Seedtime*, "ought to be communities, miniature commonwealth or states, as they were in the Middle Ages. How otherwise can they impart the preparation necessary for adult life?" It was a secession from Abbotsholme that led to the foundation of the second experimental school, Bedales, near Haywards Heath. The third school which sprang from the Fellowship and the Garden Cities Association was St. Christopher School, Letchworth. Just as Abbotsholme threw off Bedales, so St. Christopher School threw off Frensham Heights School at Farnham in Surrey. Both St. Christopher School and Frensham Heights aimed at affording the fullest possible community life of work and play. Another outpost of Letchworth was the Mansfield House Settlement in London.

The Utopists, laughed at and despised in their day and age, have not been without their effect on history. Bacon was the real father of the Royal Society, the Owenite socialists were the fathers of the garden city movement, and the Fellowship of the New Life incubated a number of experimental schools.

To-day the community planners have a real relevance. This is an age of community centres, satellite towns, group dynamics, sociometry. One of the major intellectual attractions is the rediscovery of a community of Essenes. Another is the current preoccupation in psychology and psychiatry with what is called group therapy. Sociologists, too, are affected: Pitirim Sorokin has established at Harvard a Research Centre in Social Altruism. The Christian Church itself has acquired an enhanced awareness of the importance of community relationships. Utopian literature is well known; what is not so well known are the literary by-products of Utopist endeavour. One is "The Pilgrim's Progress" and another is "The Vicar of Wakefield".

OBITUARY

Dr. G. R. Bisby

Guy Richard Bisby, plant pathologist and mycologist, who died at his home in Staines, Middlesex, on September 3, was born at Brookings, South Dakota, on August 17, 1889. He came of farming stock, and like many of his contemporaries worked his way through the university, graduating B.S. from South Dakota State College, 1912, and becoming an M.A. of Columbia University, 1917. In the following year he was awarded the degree of Ph.D. by the University of Minnesota for a thesis on *Fusarium* diseases of potato. During 1916–20 he was instructor, then assistant professor in plant pathology in the University of Minnesota, and later, until 1936, professor of plant pathology and plant pathologist in the Manitoba Agricultural College, Winnipeg (where he took Canadian nationality). He spent 1921–22 in England at the Imperial Bureau of Mycology, and in 1937 returned to the Imperial (now Commonwealth) Mycological Institute, Kew, where he became senior assistant mycologist—a post he held until his retirement in 1954.

The author of more than a hundred books and papers on plant pathology and mycology, Dr. Bisby is best remembered as a taxonomist. His strength in this field was an ability to make up his mind, and this, combined with a systematic approach and prodigious industry, gave him the knack of bringing to a conclusion any project on which he might engage. In a notable series of collaborations he set the pace and brought to fruition catalogues of the fungi of Manitoba, India and Ceylon, lists of the Pyrenomycetes, Hyphomycetes and rusts of Great Britain, and a "Dictionary of the Fungi".

He was interested in many different groups of fungi, and although he will be perhaps particularly remembered for his studies on the Hysteriales, he made important contributions to our knowledge of the Hyphomycetes, especially *Stachybotrys* and *Trichoderma*. He was in charge of the rust collections at the Commonwealth Mycological Institute, and his ready help in identifying specimens and his prompt replies to inquiries will be remembered with gratitude by many overseas plant pathologists. One result of Dr. Bisby's interests in nomenclature was the most useful little book, "The Taxonomy and Nomenclature of Fungi", 1945 (2nd edition, 1953).

Of a retiring disposition, Bisby was seen at his best talking 'shop' in his room at the Institute or in his garden (which was as well-ordered and as weed-free as his taxonomy); but he had many interests, including chess, archæology, the clarinet and, like many taxonomists, stamp collecting. One of his chief hobbies, due in part to a wide circle of friends in North America, was correspondence, and many mycologists welcomed the sight of his clear handwriting and the signature written with such dash and flourish.

Dr. Bisby received a number of honours. He was vice-president of the British Mycological Society, a member emeritus of the American Phytopathological Society, and in 1956 the University of Minnesota awarded him the gold medal for outstanding achievements.

G. C. Ainsworth

NEWS and VIEWS

The Woodrow Wilson National Fellowship Foundation

Sir Hugh Taylor, dean emeritus of the Graduate School of Princeton University, has been appointed first president of the Woodrow Wilson National Fellowship Foundation. Dr. Hans Rosenhaupt, assistant provost of Columbia University, has been appointed national director of the Foundation. The headquarters of the Foundation are at 32 Nassau Street, Princeton, New Jersey.

The Woodrow Wilson National Fellowship Foundation was founded in 1957 with the main objective of recruiting outstanding students for careers as college teachers. In 1957, after the Wilson Fellowships had been jointly underwritten for five years by thirty-seven American universities and by grants from the Carnegie Corporation and General Education Board, the present programme began with a grant of 24,500,000 dollars from the Ford Foundation for a five-year period. During the first year of its operation the Foundation granted fellowships to nearly a thousand students in the United States and Canada who will graduate this year.

H. W. M. Olbers

Heinrich Wilhelm Matthias Olbers, who was born at Arbergen, a village on the Weser near Bremen, two centuries ago on October 11, 1758, was an amateur astronomer who, even after his discoveries had been accepted and acclaimed, continued his medical practice. The son of a minister, he studied mathematics and medicine at the University of Göttingen, where he graduated M.D. in 1780 with a thesis entitled "De oculi mutationibus internis". While still a student, he devised the first satisfactory method of calculating the orbit of a comet in 1779.

His "Abhandlungen über die leichteste und bequemste Methode die Bahn eines Kometen zu berechnen", with a table of eighty-seven calculated orbits, which was made public by Baron F. X. von Zach in 1797, won him universal fame. A second edition was issued in 1847 and a third in 1864. Olbers took up medical practice at Bremen in 1781, but devoted the greater part of each night to astronomy, having fitted the upper portion of his house as an observatory. On January 1, 1802, he rediscovered Ceres, the first minor planet discovered by Giuseppe Piazzi in 1801, and on March 28 observed the second asteroid Pallas, followed by Vesta in 1807. His theory that these planetoids are fragments of a quondam planet, disrupted by internal explosion or by the impact of a comet, was sanctioned by William Herschel, but is no longer accepted. In 1815, Olbers discovered a new comet which bears his name and which has a period of 74 years. He showed that the tail of a comet consists of a filmy vapour driven off from the head by a repulsive force in the Sun, which is now known to be the pressure of solar radiation. He retired from medical practice on January 1, 1823, and in 1830, the jubilee of his graduation, he received an honorary doctorate from the medical faculties of Berlin, Bonn and Copenhagen. He died on March 2, 1840, in his eighty-second year.

World Data Centre for Rockets and Satellites, Slough

A World Data Centre for Rockets and Satellites is now operating at the Radio Research Station of the Department of Scientific and Industrial Research at Ditton Park, Slough, Bucks. This is the third of three centres established under the International Geophysical Year arrangements for centralization of this type of information. Previously there have been rocket and satellite data centres only in Moscow and Washington, and it was agreed at the recent Moscow meeting of the Special Committee for the International Geophysical Year to accept a British offer of a third rocket and satellite centre. The Radio Research Station is an appropriate place for such centres because many satellite experiments are concerned with studies of the ionosphere. Studying the travel of radio waves from satellite transmitters is one way of gaining information about the ionosphere. Research workers at the Radio Research Station and its Singapore sub-station are engaged in such work. Data from the British investigations will be collected by the Slough Data Centre and exchanged with the other data centres in the United States and the U.S.S.R. Information on International Geophysical Year rocket flights and the published reports of investigations will also be collected. All data will be available for inspection and use by workers in the respective scientific subjects under arrangements which apply to all world data centres.

Reorganization of the Admiralty Material Departments

The First Lord of the Admiralty announced in the House of Lords on December 19, 1957, a reorganization of the Material Departments under the Controller of the Navy, following upon the report of Sir Barclay Nihill's Committee. The reorganization was completed on October 1 when the new Ship Department was set up. The work of the Controller's departments will then have been reorganized into four large material departments (concerned, respectively, with ships, weapons, aircraft, dockyards and maintenance), each headed by a director-general, and a small group of scientific departments headed by the Chief of the Royal Naval Scientific Service, who will work under the immediate guidance of the Deputy Controller (Research and Development). This group is broadly responsible for basic research and development, the provision of scientific staff and advice to the material departments, and the planning and co-ordination of Admiralty research programmes. Applied research and development will continue to be carried out at the various scientific establishments. The superintendents of those establishments, which will form a part of the supporting services of the new Ship Department, will be responsible for the work of their respective establishments to the Director General, Ships, through the directors of the appropriate professional divisions. The senior scientific officer serving in the Department will act as chief scientific adviser to the Director General and to the directors of Divisions.

B.B.C. Television

An interesting addition to the publications of the British Broadcasting Corporation is a booklet entitled "B.B.C. Television—a British Engineering Achievement" (pp. 64. London: B.B.C., 1958. 2*s.* 6*d.*). This is a very well produced and copiously illustrated review of the development and present attainments of the Corporation's television service. Reference is made to the early experimental transmissions begun in 1929, and to the report of the Postmaster-General's Television Committee issued in January 1935, which was followed by the opening of the first public television service in the world during the succeeding year. A brief outline of the principles of television is followed by an up-to-date picture of the television facilities which have been built up and are now in use by the B.B.C., with a full description of the new Television Centre now under construction near Shepherd's Bush. A map in colour showing how B.B.C. television broadcasts reach more than 98 per cent of the population, and advice on how to get the best reception of the B.B.C. television service are other items in this booklet. The effects of various forms of interference are also described and illustrated. A mobile television control room is illustrated together with the various methods of telerecording, including the most recent 'vision electronic recording apparatus' (VERA) which will shortly be put into general service. Outside broadcasts account for approximately one-sixth of the B.B.C.'s television programme output. Apart from dealing with activities in Britain, an account of the growth of the international exchange of television programmes known as Eurovision, which was pioneered by the B.B.C. and Radio Diffusion Télévision Française, is supplemented by a map showing the Eurovision network.

Electronics, Radio and Telecommunications

Considerable progress is being made in the publication of English translations of Russian scientific and technical literature. Three journals have recently become available published in English translation on the initiative of the Massachusetts Institute of Technology and the Pergamon Institute, assisted by a grant-in-aid from the United States National Science Foundation. One of these is *Telecommunications* (No. 1, 1957. Pp. 1–94. First English issue. Issued in parts, approximately 1,000 pages per annum. Annual subscriptions: to individuals, 15 dollars

(107*s*.) ; to libraries, research laboratories, Government departments and industrial organizations, 30 dollars (214*s*.). New York and London : Pergamon Press, 1958). The first issue contains a number of articles on various aspects of radio and line telegraph and telephone matters. It also includes a brief review of the characteristics of U.S.S.R. State television standard for black-and-white television broadcasting on a 625-line system.

The other two journals appear to be longer established. *Radio Engineering and Electronics* (2, No. 2, 1957. English edition. Pp. 1–183. Approximately 2,500 pages per annum. Annual subscriptions : to individuals, 22.50 dollars (160*s*.) ; to libraries, research laboratories, Government departments and industrial organizations, 45 dollars (320*s*.). New York and London : Pergamon Press, 1958) contains fourteen articles related to various subjects in electronics, including wave-guides, dielectrics and cathode-ray tubes. A brief article on the life and work of Heinrich Hertz, in relation to the centenary of his birth (February 22, 1857), is also included. *Radio Engineering* (12, No. 8, 1957. First English issue. Pp. 1–112. Approximately 2,500 pages per annum. Annual subscriptions : to individuals, 22.50 dollars (160*s*.) ; to libraries, research laboratories, Government departments and industrial organizations, 45 dollars (320*s*.). New York and London : Pergamon Press, 1958) is devoted to technical and theoretical aspects of the subject of its title, and is the official publication of the A. S. Popov Technical Society of Radio Engineering and Telecommunications.

Coryndon Memorial Museum, Nairobi

It is pleasing to note that the annual report for 1957 of the Coryndon Memorial Museum at Nairobi makes no reference to any restrictions on its work by Mau Mau activities (pp. 28+1 plate. 1958. Nairobi : Museums Trustees of Kenya and the Coryndon Memorial Museum). Instead, the whole energy of the staff has been turned to constructive measures, and several new exhibits have been prepared. The Bongo habitat group has been enlarged and new groups depicting Abbot's Duiker and Klipspringer installed. Exhibits dealing with the bats of East Africa, melanism and albinism proved popular. Additional marine and freshwater fish were shown in the aquaria, the most outstanding being a young shark and several species of dragon fish. In the Gandhi Hall the mineral and rock exhibits were augmented, many new geological maps were displayed and a new exhibit dealing with recent discoveries at Olduvai Gorge was placed on view. Stamps and postal literature have now been included in the collections.

Forestry in Ulster

An illustrated pamphlet, "Forestry in Northern Ireland" (pp. 20. Belfast : Ministry of Agriculture, 1958), which includes a map of these forests, issued by the Ministry of Agriculture, Northern Ireland, appears to be admirably designed to serve its purpose as a piece of public relations policy. It sets forth clearly and concisely the origin and development of the State forests, the purpose they serve and the policy pursued in their management. At the same time, it indicates their need of public understanding and support, as well as the nature of that support and the contribution to public amenity and enjoyment which the forest parks now offer. A regulation made under the Forestry Act (Northern Ireland), 1953, declared Tollymore Park, near Newcastle, County Down, open to the public as a forest park, and the Park, which covers about 1,200 acres, was officially opened on June 2, 1955.

Careers in the Plastics Industry

Under the title "Careers in Plastics" (pp. 20. London : The Plastics Institute, London, 1958), the Plastics Institute has issued, for the guidance of senior scholars and those responsible for advising them on the choice of a career, a pamphlet setting forth the opportunities presented by the rapidly growing plastics industry, particularly for those with technical qualifications or scientific training. Besides a summary of the technical appointments available, the pamphlet includes information on the constitution of the industry, and particulars of how to enter it, and the technological, professional and academic qualifications desirable (with a chart indicating the various routes by which they may be obtained) and details of teaching centres where approved courses for the qualifications of the Plastics Institute can be pursued. Some indication is given of salaries and prospects, and there is a short appendix on the pupil apprenticeship scheme for the industry, which shows incidentally how well placed a professional body is to press for the adjustment of apprenticeship conditions to meet modern needs.

The National Institute for Research in Dairying

Research workers in many branches of science, practical farmers and agricultural advisory officers will all find something of interest and importance in the annual report of the National Institute for Research in Dairying for 1957 (pp. 160. Shinfield : National Institute for Research in Dairying, University of Reading, 1958. 4*s*.). It is largely devoted to a concise account of the research work done in each of the various departments and sections of which the Institute is composed, while for those who do not require to have so much detail a brief outline is given of many of the recent research findings. The subjects dealt with in the brief outline range from such immediately practical problems as labour-saving devices in feeding lactating sows and grazing management of lactating cows, to basic work such as that on the utilization of amino-acids by the isolated perfused bovine udder and the deoxyribonucleic acid content and histology of the mammary gland. Mention of work done by the Statistical Section on the derivation of general orthogonal polynomials helps to illustrate the breadth of the Institute's programme of work, and in this atomic age perhaps it is not surprising to find that the problem of salvaging milk which has been contaminated with radiostrontium has already been studied. The report gives a detailed list of 151 papers most of which were published in 1957.

The Marshall Pulse Height Analyser *HS* 100

The Marshall pulse height analyser has been developed at the Airport Works of Marshall of Cambridge under licence from the National Research Development Corporation, with the object of producing a first-class British instrument exhibiting all the characteristics of existing analysers at a fraction of the cost but retaining their accuracy and achieving the utmost reliability. This is effected by the use of the Hutchinson–Scarrott principle, using computer techniques for the storage of information performed in serial manner using two torsional acoustic delay lines. This system is inherently simpler in construction and less extravagant in components than the core memory type of analyser. The facilities include a visual display and automatic read-outs in both analogue and digital systems. The analyser will accept a wide range of pulses of either sign up to a maximum mean counting rate of 1,600 pulses per second. The input pulses may be back-biased at the input to the amplifier, when a gate is provided for coincidence and anti-coincidence work. The memory is divided into either 100 or 150 channels, for which the energy scale may be either linear or exponential, the latter case giving greater resolution at the lower energy end of a spectrum. Another extremely useful facility is the ability of the instrument to subtract counts from a spectrum already in the memory. In conjunction with the live-time integrator, which is necessary at a high counting rate, the background count can automatically be subtracted from a spectrum, leaving the true count in the memory. A total count scaler records the total number of pulses analysed by the instrument. Further information concerning this analyser can be obtained from Messrs. Marshall, The Airport, Cambridge, England.

International Measurements Conference

An International Measurements Conference organized by Hungarian, Polish and Soviet scientific societies is to be held in Budapest during November 24–30. Plenary sessions are to be concerned with papers on the more fundamental matters of units and standards of measurement, together with techniques of measurement and instruments in their broadest aspects. Section meetings are to discuss papers on instruments and measuring methods for: mechanical quantities and precision mechanics; light and colour; temperature, flow, humidity and other process parameters; electrical and magnetic quantities; electronics; physico-chemical quantities; X-rays and nuclear radiations. Papers on economic, organizational and educational aspects of industrial instrumentation comprise a third group. The Proceedings are to be published. During the conference the Hungarian Industrial and Scientific Instruments Exhibition will be open to participants. Further details are obtainable from the Secretariat, Budapest 5, Post Office Box 3.

University News: Birmingham

The following appointments have been made: Dr. Janet S. D. Graham, lecturer in botany; D. P. Howson, lecturer in electrical engineering; B. D. Richardson, lecturer in civil engineering; Sir Francis G. W. Knowles, Bart., and A. W. Rogers, lecturers in anatomy; H. A. Ellis and D. J. Parish, lecturers in pathology; J. D. Cumming, lecturer in physiology.

London

Dr. W. O. James, reader in botany in the University of Oxford, has been appointed University professor of botany and head of the Department in the Imperial College of Science and Technology (see *Nature* of October 4, 1958, p. 916). Mr. H. Charnock, principal scientific officer in the Royal Naval Scientific Service, has been appointed to the readership in physical oceanography tenable at the Imperial College of Science and Technology. Dr. Karl Wilson, lecturer in botany in Birkbeck College, has been appointed to the readership in botany tenable at the College. The title of Henry Mark Pease (Standard) professor of telecommunications in the University of London has been conferred on Dr. E. C. Cherry in respect of his post at the Imperial College of Science and Technology.

Announcements

Sir Rudolph Peters, professor emeritus of biochemistry in the University of Oxford, and lately director of the Agricultural Research Council's Institute of Animal Physiology, Cambridge, has been appointed president of the International Council of Scientific Unions in succession to Dr. Lloyd Berkner.

The Niels Bohr Gold Medal, awarded for outstanding achievement in the field of peaceful uses of atomic energy, was presented to Sir John Cockcroft in Copenhagen on October 7.

Vice-Admiral Sir Frank Mason, formerly Engineer-in-Chief of the Fleet, has been appointed a member of the Council for Scientific and Industrial Research.

Dr. J. G. Malloch, representing Canada, has been appointed chairman of the Executive Council of the Commonwealth Agricultural Bureaux in succession to Mr. T. Swaminathan, who represented India. Mr. A. Perera, representing Ceylon, has succeeded Dr. Malloch as vice-chairman.

Dr. Lewis E. Lloyd, associate professor of nutrition in the Macdonald College of the McGill University, has been awarded the Underwood Fellowship by the Agricultural Research Council, to continue his studies of the metabolism of rumen micro-organisms. For the greater part of the year, Dr. Lloyd will work at the Rowett Research Institute, Aberdeen.

The seventh Coal Science Lecture of the British Coal Utilization Research Association will be given by Sir Charles Goodeve at the Institution of Civil Engineers on October 15. It will be entitled "Carbon: the Key to Metallurgy". Further information can be obtained from the Association at Randalls Road, Leatherhead, Surrey.

A series of lectures by leading experts on space research and technology is being organized by the University of Maryland. The lectures will be held on Monday evenings during October 13–December 1. Further information can be obtained from the Director of Institutes, University of Maryland College of Special and Continuation Studies, College Park, Maryland.

The Journées Métallurgiques d'Automne of the Société Française de Métallurgie will be held in Paris during October 20–25. Further information can be obtained from the Société at 25 Rue de Clichy, Paris 9^{e}.

The next award of the Meldola Medal, which is the gift of the Society of Maccabæans, will be made early in 1959 to the chemist who, being a British subject and less than thirty years of age on December 31, 1958, shows the most promise as indicated by his or her published chemical work brought to the notice of the Council of the Royal Institute of Chemistry, 30 Russell Square, London, W.C.1, before December 31, 1958. Letters of application or recommendation should be accompanied by six copies of a short statement on the candidate's career (date of birth, education and experience, degrees and other qualifications, special awards, etc., with dates) and of a list of titles, with references, of papers or other works published by the candidate, independently or jointly, preferably with one reprint of each published paper of which copies are available.

SCIENTISTS IN THE PUBLIC SERVICE IN BRITAIN

SPECIAL PROMOTIONS

FURTHER special posts have been created in the Civil Service under provisions included in the White Paper on the Scientific Civil Service (Cmd. 6679; 1945) to provide for the promotion of individual research workers of exceptional merit. The promotions, which are effective from July 1, include the following:

Chief Scientific Officer

DR. N. P. ALLEN has been superintendent of the Metallurgy Division at the National Physical Laboratory, Teddington (Department of Scientific and Industrial Research) since 1944. He was a lecturer in the University of Birmingham, where he obtained the degree of D.Sc. in 1934. As a research metallurgist with the Mond Nickel Co., Ltd., he made important contributions to the study of alloy steels and to the development of creep-resistant alloys for gas turbines. At the National Physical Laboratory he has been responsible for work on the metallography of uranium, the brittle fracture of exceptionally pure iron and the influence of additions on it, the development of improved materials for steam power plant and the processes taking place during the fatigue and creep of metals. He has been interested in the metallography of the newer metals such as titanium and niobium, and in the application of radioactive tracers, electron microscopy and soft X-ray spectroscopy to metallurgical problems. He was elected Fellow of the Royal Society in 1956.

Deputy Chief Scientific Officers

DR. I. J. GOOD joined the Government Communications Headquarters in 1941, leaving in 1945 to lecture in mathematics in the University of Manchester. He returned to the Government Communications Headquarters in 1948, and has made notable original contributions to statistical theory and the development of advanced methods of application to Service problems.

MR. H. L. GREEN joined the Physics Section of the Chemical Defence Experimental Establishment in 1922. In January 1949 he was given special promotion on individual merit to the grade of senior principal scientific officer. He has been engaged, and is a recognized authority, on problems related to particulate clouds and filtration, developing many novel devices and techniques for sampling and assessing aerosols and conducting research which has led directly to widely used filter systems including those in respirators. Of late years, he has also been working on problems of radiological defence, including the physics of nuclear fall-out. He has served on Committees of the Department of Scientific and Industrial Research, the Home Office and Medical Research Council and (with W. R. Lane) is author of a recent book, "Particulate Clouds: Dust, Smokes, and Mists".

MR. A. R. HOWELL joined the Royal Aircraft Establishment in 1938. He was a research engineer with Power Jets (Research and Development), Ltd., during 1944–46. On the conversion of the firm he joined the National Gas Turbine Establishment, and since 1949 has been, as a senior principal scientific officer, head of the Aerodynamics Department. Mr. Howell's career has been devoted mainly to the aerodynamics and performance of gas turbines and he is well known for the analysis on which the design rules for the modern axial compressor are based. He has made original contributions on ejectors, theory of aerofoils in cascades, flutter of compressor blades and engine-assisted lift. He is a Fellow of the Royal Aeronautical Society.

DR. J. G. NAGELSCHMIDT, who joined the Safety in Mines Research Establishment in 1949, is a mineralogist of international reputation and is now engaged on research on the mineralogical aspects of pneumoconiosis. He has made important contributions to the study of the toxicity of dusts, as well as in the metallurgical and chemical fields, where he is both an expert and an authority. He has been a pioneer in the application of X-ray diffraction techniques to the study of clay materials, in the application of new mineralogical techniques to the study of dusts responsible for lung disease, and in the application of the electron microscope to the study of clay minerals and dusts. He has developed new techniques for the quantitative mineralogical analysis of small dust samples and for the identification of mineral particles too small for identification with the optical microscope. He is secretary of the Medical Research Council's Sub-Committee on Dust which co-ordinates pneumoconiosis research in Britain; he is a member of the Council's Industrial Pulmonary Diseases Committee, and of its working party on atmospheric pollution. He is also a member of the committee of the Clay Minerals Group of the Mineralogical Society.

MR. J. S. SAWYER, assistant director (dynamical research), joined the Meteorological Office in 1937. He joined the new Forecasting Research Division at Dunstable in 1948, becoming assistant director in 1953. In the past ten years he has made major contributions to the study of rainfall, depressions, the tropopause and the dynamics of fronts, as well as to the revolutionary subject of dynamical forecasting by the numerical integration, using electronic computing aids, of sets of differential equations derived from basic fluid dynamics and thermodynamics. Developments in this promising field are likely to be the main concern of his group for some years to come.

DR. W. S. STILES's original work at the National Physical Laboratory was concerned with problems of vision arising in illuminating engineering, and he did valuable work on glare from car headlights and on street lighting. From these applied problems, he was led to a series of basic studies of the threshold sensitivity of vision under a wide range of stimulus conditions. One outstanding result was the resolution of several mechanisms concerned in colour vision, by methods independent of the traditional colour-matching approach. Dr. Stiles is probably best known as the discoverer, with his colleague, Dr. B. H. Crawford, of the directional sensitivity of the retina—the Stiles–Crawford effect. Dr. Stiles's investigations during the Second World War of such Service problems as visibility and visual scanning methods was recognized by his appointment in 1946 as O.B.E. Since then he has resumed his investigations of vision, and his latest contribution to the subject is a large-scale determination of average colour-matching properties. In 1957 he was elected Fellow of the Royal Society for his work on vision.

MR. C. K. THORNHILL, joining the Government service in 1939, worked successively at the Projectile Development Establishment, the Ordnance Board and the Armament Research and Development Establishment. In 1952 he was given special promotion on individual merit to senior principal scientific officer. Mr. Thornhill is a versatile applied mathematician. His early research was on the development and lethality of rockets, external and internal ballistics, gun-heating and gun-erosion, and led to the award of the U.S. Medal of Freedom for meritorious service in the Second World War. More recently, he has contributed to several fields of weapons research and has become a recognized authority on steady and unsteady gas dynamics and on explosion phenomena, working particularly of late on the effects of atomic explosions. Mr. Thornhill served on the Compressible Flow Tables Panel of the Aeronautical Research Council, and contributed portions of its well-known published collection of tables and graphs.

MR. R. A. WELLS is in charge of the Radiochemistry Group at the National Chemical Laboratory of the Department of Scientific and Industrial Research. He has played a large part in the foundation of analytical techniques based on chromatography and applied to inorganic materials, now used in Australia, South Africa, Rhodesia, Portugal and Canada. These researches constitute an outstanding achievement in analytical procedures during the past decade. He also devised field techniques for the determination of various metals in river waters. In hydrometallurgical research he has developed new methods for the concentration and extraction of metals, for example thorium, by the use of modified celluloses such as the phosphorylated product; and a series of selective ion-exchange resins whereby gold can be recovered from cyanide liquors. He has on occasions acted as a consultant to the Atomic Energy Authority on flow-sheets and costing in connexion with full-scale industrial uranium-extraction plants.

Senior Principal Scientific Officers

MR. P. J. E. FORSYTH, of the Metallurgy Department, Royal Aircraft Establishment, is a skilled experimenter who has done outstanding work on fundamental aspects of the fatigue of metals and alloys.

DR. L. GRUNBERG is engaged in the Lubrication Division at the Mechanical Engineering Research Laboratory of the Department of Scientific and Industrial Research on the chemical and physico-chemical aspects of lubrication in relation to the wear of the rubbing surfaces of machine components. He is distinguished for his work on the study of the emission of charged particles occurring on freshly deformed metal surfaces.

DR. F. E. JONES is a member of the Chemistry Division at the Building Research Station of the Department of Scientific and Industrial Research, where he has worked on the chemistry of cement and concrete, and in particular on the products formed on hydration; and on the corrosion of metals under the particular conditions that arise in buildings.

DR. D. MCK. KERSLAKE, of the R.A.F. Institute of Aviation Medicine, is in charge of the Climatir Research Laboratory. His work in recent years hac been mainly directed towards the protection of air-crews against extremes of cabin temperature, and in this particular field he has become well known throughout Britain.

DR. T. S. MOSS, of the Radio Department, Royal Aircraft Establishment, has carried out much original experimental and theoretical work on the properties of semi-conductors and is a leading authority on photo-conductivity and infra-red detection.

DR. C. A. PARKER is head of the general chemistry division at the Admiralty Materials Laboratory, which includes in its programme radiochemistry, X-ray techniques and ferrite chemistry. He is now specializing in photo-chemistry.

MR. H. H. B. M. THOMAS, of the Aerodynamics Department, Royal Aircraft Establishment, is well known as an authority on the stability and control problems of aircraft.

MR. P. R. WALLIS, working at the Admiralty Signal and Research Establishment, has been responsible for much of the development of radar techniques for guided weapon systems.

DR. JOHANNA WEBER, of the Aerodynamics Department, Royal Aircraft Establishment, has worked on a variety of problems in classical theoretical aerodynamics, including the theory of lifting surfaces in supersonic flow and the minimization of wave drag.

DR. J. G. WHITMAN, of the Mechanical Engineering Experimental Establishment, has a wide background of engineering research, especially in problems of welding and of the fatigue and failure of metals and metal structures.

Similar promotions have been made by the Agricultural Research Council, as follows:

Deputy Chief Scientific Officer

DR. ROBERT BROWN, after graduating with first-class honours at the Imperial College of Science and Technology, London, in 1936, held various teaching appointments. He was a senior lecturer in botany at the University of Leeds during 1946–49, when he became reader in plant physiology. He joined the staff of the Agricultural Research Council in 1953 on his appointment to the directorship of their Unit of Plant Cell Physiology at Oxford. Dr. Brown's researches are principally directed to the cellular phenomena involved in plant growth and differentiation. He has given particular attention to the meristems, analysing development in terms oy cell division and cell expansion. In October 1958 Dr. Brown will become head of the Cell Biology Department of the John Innes Horticultural

Institution. Dr. Brown was elected Fellow of the Royal Society in 1956.

Senior Principal Scientific Officers

Dr. H. F. **Barnes** is deputy head of the Entomology Department at Rothamsted Experimental Station. He is a world authority on gall midges and he has published widely on these and other insect pests.

Dr. K. L. **Blaxter**, head of the Nutrition Department of the Hannah Dairy Research Institute, has been particularly concerned with research on problems related to the energy exchange of large farm animals.

Dr. G. A. **Levvy** is head of the Enzymology Department of the Rowett Research Institute. He is working in the field of the biochemistry of the glycosidases of their inhibition by aldonolactones.

One similar promotion to senior principal scientific officer has been made by the Atomic Energy Authority. Dr. P. E. **Cavanagh**, who is head of the beta-ray spectrometer group at Harwell, doing mainly basic research but also responsible for some technical developments, including that of the recording of nuclear-pulse data on magnetic tape. Achievements in basic research include the original observation of the double Compton effect—a higher order process in quantum electrodynamics—and the first accurate measurements of electron polarization violating parity.

The Development Commission has similarly promoted Dr. H. **Barnes** to senior principal scientific officer. Dr. Barnes has been a research chemist on the staff of the Marine Station, Millport, since 1946, and is well known for his work on physical and chemical oceanography. In addition, he has developed underwater television apparatus and is an authority on the biology of barnacles.

OCCUPATIONAL PSYCHOLOGY

AMONG the best-attended meetings in Section J (Psychology) of the British Association this year were those held during the occupational psychology session on September 1. Four papers were given in the course of the morning on which the session was held. Anyone looking for continuity or what the papers had in common might have remarked that the first dealt with competitive entry into industry in youth—trade apprentice selection—while the last dealt with retirement—largely compulsory retirement—from industry because of age. From another point of view there was also a certain similarity between the first three papers. All were, in a sense, directly concerned with problems of inspection; the first, 'inspection' of suitability for trade-apprenticeships in shipbuilding; the second, routine inspection of industrial products; and the third, systems of fault-finding in electronic equipment.

In the first paper, by Mr. J. G. McComisky (University of Hull) and Dr. P. P. Daws (University of Edinburgh), the introduction and development of an apprentice selection scheme in a Glasgow shipyard were described. In 1956, when the firm approached the Applied Psychology Unit of the University of Edinburgh for assistance, only about half the boys put on the firm's pre-apprentice trade courses were reaching the necessary standards to become indentured. In round figures, to obtain its quota of about 80 trade apprentices each year, the firm was obliged to put about twice this number through its pre-apprentice courses. All boys entered on courses were regarded as being likely to succeed. Following a review of the position when the firm asked for assistance, the following programme was decided on: (1) That immediate steps be taken to check the effectiveness of the firm's own system of initial selection. This consisted of an arithmetic test and an interview by the firm's apprentice supervisor. The arithmetic test was checked and found to be faulty. It was discarded and a new arithmetic test introduced. (2) That a selection scheme involving psychological testing be run for an experimental period of one year, and if the results warranted it, that this should replace the firm's existing system of selection. (3) That the selection scheme be developed in a way which would enable the firm's apprentice supervisor to run it with the need for no more than occasional advice and guidance from a psychologist.

Before experimental selection began, all second-year trade apprentices in the firm were given the battery of psychological tests which it was proposed to use during the experimental phase of the scheme, the object being to see what relation there was between scores on the various tests and foremen's assessments of the second-year apprentices. A meeting was also arranged with the instructors on the pre-apprentice courses, the object being to enlist the co-operation of these in the projected scheme right from the beginning, and also to obtain information on the kinds of difficulties met by both instructors and boys on the pre-apprentice courses.

With the information and insights obtained from these sources experimental selection began. This, in practice, entailed giving all the boys on the firm's courses the battery of tests decided on, interviewing each for about 15 minutes, and then predicting whether or not the particular boy was likely to pass the course. An attempt was also made to spot particularly bright boys, as the firm was anxious to put these in line as early as possible for technical advancement in the firm. The degree of success in predicting failures and bright boys in the experimental year was encouraging enough to justify the procedure being put into effect as the official apprentice selection scheme of the firm.

In the first year of actual selection wastage on the courses dropped considerably: on the shipbuilding side—one of the two main divisions of the firm's apprenticeship system—it dropped from 42 to 22 per cent with a reduction of 33 per cent in the number of boys entered on courses. On the marine engineering side, the smaller division of the firm's apprenticeship system, the results were not as good, but the failure-rate in the first year of real selection dropped to

41 from 55 per cent in the previous year with the prospect of being further reduced. Work on improving the scheme is continuing. Dr. Daws, who has been supervising it for the past two years, has just discovered, for example, from his analysis of the relationship between scores on the tests and ability on the pre-apprentice courses, that the combined score of the five most effective tests in the battery—a verbal and a non-verbal intelligence test, a test in spatial ability, one in mechanical comprehension and one in arithmetic-mathematics—forms a most effective predictor when used alone. The refinement and adoption of this predictor will considerably simplify the selection procedure as a whole.

Since the full introduction of the scheme eighteen months ago it has been run by the firm's apprentice supervisor with the advice of Dr. Daws where necessary. In terms of cost the scheme has turned out to be comparatively inexpensive in both time and materials.

In the second paper, Mr. R. M. McKenzie (University of Edinburgh) described some of the factors making for good or bad relations between inspectors in industry and the workmen concerned. Some of the factors described involved considerations which were mainly economic, as, for example, where a bonus is paid only for work which has passed the inspector; other factors derived from the organization of the particular factory and the nature of the product, for example, in 'in-process' inspection where the particular products are checked while they are still being made so that any error of man or machine can be put right before a lot of bad work has been done. A third group of factors originate in the more purely human aspects of inspection, the fact that inspection with the prospect of adverse criticism is going on at all, whether or not the inspector is an older person than the general run of those whose work he is inspecting, what length of service he has had with the particular firm, and so on.

A consideration often discussed in connexion with inspection in industry is the nature of the inspector's qualifications for the job. Since the production man must be able to accept criticism from his inspector without losing face, it is a great help if the inspector is at least as well qualified technically as the operator or the charge-hand. He may, however, not need this skill to do the actual inspection. As Mr. McKenzie pointed out, "Many a man can grade an egg who could never lay one, but the man who grades the eggs can tell which hens are no use".

Another aspect of inspection which Mr. McKenzie dealt with was the frequent accusation that inspectors are inconsistent. A number of experiments which he himself had carried out showed that there is more to this criticism than an attempt to save face. In an experiment, for example, in checking sub-assemblies, one inspector rejected five out of a batch of fifty in one day but nine in the next. Another inspector rejected thirteen of the same batch. Two inspection-supervisors, as judges, considered that, in fact, eight were defective. The results of Mr. McKenzie's experiments indicate clearly that the consistency of inspectors should not just be taken for granted. Factors which work against consistency include the fact that very often standards have simply not been clearly laid down. Often, too, the training of inspectors could be improved. Sometimes physical conditions such as the placing of lights or even the boredom of repetitive inspection are factors in poor consistency. It might be asked: Why do not inspector-supervisors check the accuracy of their inspectors? The reason, in practice, is usually found to be that very often relations with production are strained, and, as a consequence, the inspector-supervisor tends to side with his inspectors. The result is that he sees himself first as an inspector and only very secondarily as a supervisor over inspectors.

In his summing up, Mr. McKenzie stressed the importance when picking inspectors of paying particular attention to whether or not they are likely to be acceptable to those over whom they are exercising authority. This is quite crucial since inspection is not just of the product but of the man who has made it; because of this a reasonable working relationship must be established between the two sides. The quite anomalous position of the inspector in regard to both authority and pay in industry at the present time makes this all the more imperative. The inspector, for example, is not the workman's supervisor; very often he has only the same rank as the operator himself, and in many cases receives even less pay. This makes a naturally difficult job even more exacting and underlines the need for appreciation of the importance of such qualities as tact and forbearance in the inspector in industry.

In the third paper, Mr. H. C. A. Dale (University of Cambridge) described an experimental programme on method of approach in fault-finding on which he is engaged. Mr. Dale began by pointing out that the overall efficiency of electronic equipment usually depends on the rapidity with which faults can be located and repaired. In other words, a good deal of the maintenance on it is remedial. Actual repair work usually presents no problem, but fault location does, and good fault-finders are in short supply. Mr. Dale's own research on the subject was aimed at determining the best way of training technicians to do fault-finding in an economic way.

Before addressing himself to the specific aspects of the problem, Mr. Dale gave a short description of basic design in electronic equipment as follows: electronic equipment consists basically of units arranged in chains. A signal or message flows through these chains, each unit making a slight change in it, rather like the way in which small changes are made to the product in a mass-production factory. The fault-finder has to search first for the chain which is faulty, then for the faulty unit, and finally for the component within this unit which is causing the trouble.

The question Mr. Dale then asked was: Can we expect persons to know the best way of searching in a system of this kind, or do they have to be taught? In actual location of faults in electronic equipment when done in the most efficient way, three steps are essential: (1) discover which chain is faulty; (2) locate the faulty unit; (3) find, within this unit, the faulty component.

Put briefly, the golden rule is: general questions are asked first, specific ones later. Mr. Dale then described the results of one of his experiments the main object of which was to see how far this systematic kind of fault-finding is adopted in actual practice. First, he set up laboratory fault-finding problems which involved searching in the same way as in the case of actual electronic equipment. In the particular experiment described, no more than six moves were necessary to locate the fault. The task was given to twenty-four subjects. All were thoroughly familiar with the idea of signal flow. Of the twenty-four, one only used a good solution. Eight of the twenty-four took ten moves or more. The common errors made were to move along in short steps instead of dichotomizing, to check junctions instead of chains, and to go into a chain before first finding if it contained a fault.

After describing the results of this experiment, Mr. Dale went on to tell how he checked his finding against the kind of errors made by electronic engineers searching for real faults in real equipment. The evidence shows that there is a marked tendency to make the same kinds of errors in actual practice. A study carried out by Bryan in the United States, for example, showed that of seventy of the U.S. Navy's best technicians engaged on the maintenance of wireless sets, only 17 per cent of them dichotomized.

Mr. Dale concluded his paper by saying that the results of his experiments to date and those of other relevant studies indicate clearly that we cannot expect electronic engineers to know the best way of searching for faults. They need to be taught, and, it seems, they need to be taught by instructors in technical college, not by experience.

In the last paper of the session Dr. N. R. Cowan, medical officer of health, Rutherglen, Scotland, reported the results of an inquiry into the life-histories and opinions of 443 retired men, aged 65 to 93 years, who attended a Scottish Consultative Health Centre for older people. Approximately 80 per cent of the group had been compulsorily retired. The main purpose of the report on the inquiry given in the paper was to focus attention on the traumatic effect of retirement on the health of older men.

The information for the investigation was obtained from the men on a doctor–patient basis during their visits to the Centre. An analysis of the data showed how far it could be said that the members of the group were leading a 'full' life at the time when the inquiry was made. Three criteria of 'full' were used: physical activities, mental activities, and personal relationships. Each member of the group was given a 'high', 'medium', or 'low' rating on these, and, in addition, a grading for social status based on the occupational classification list of the General Register Office. This ranges through five levels, from class I (professional) to class V (unskilled). The distribution of the group along the five levels inclined towards the lower end: there were 24 in class I (professional) and 83 in class V (unskilled).

The results of the inquiry showed that 'high' ratings on the three criteria of a 'full' life were in no case above 10 per cent for the complete group and that these were found among men in classes I and II. The proportion of 'low' ratings was quite pathetic. In the case of 'mental activities' it was 44 per cent of the group, with 'personal relationships' at 32 per cent. It was apparent that the unskilled workers in the group tended to lead equally unskilled lives.

In the course of the paper Dr. Gowan directed attention to how the harshness of the fact that our economic system does not provide employment for all who wish to work operates to such a deplorable extent against men in the age-group covered in the inquiry. As he pointed out, it is a common occurrence to see older men unsuccessfully seeking work, and also those who have passed through this stage without finding employment, unhappily resigning themselves to retirement. There are, in addition, the partial casualties of compulsory retirement—those who are forced to change their jobs late in life because of age. Of the men in the present group, 79 per cent regarded compulsory retirement as detrimental to the health of older men. One can only agree with Dr. Cowan's suggestion that until society provides some sort of education and preparation for retirement it has a social obligation to provide and subsidize congenial work for those who wish to do it.

This concluded the occupational session. It was a new venture this year in the Psychology Section of the British Association meeting and proved to be a rewarding one.

J. G. McComisky

ANALYTICAL CHEMISTRY, PHARMACY AND MEDICINE

In his chairman's address to the British Pharmaceutical Conference at Llandudno on September 15, Dr. G. E. Foster, chief analyst of Burroughs, Wellcome and Co., expressed a more than personal pleasure in the election of an analyst to the chair. Such an election, he said, was a recognition of the indispensable services which chemical analysis rendered to pharmaceutical science and industry. The names of Scheele, Baumé and Mohr illustrated how analysis and pharmacy had always, in fact, gone hand-in-hand up to the establishment of 'classical pharmaceutical analysis'—a stage which could perhaps be considered as embodied in the British Pharmacopœia of 1932.

In taking as his title "Modern Analytical Chemistry in the Service of Pharmacy and Medicine", Dr. Foster directed attention to the great pharmaceutical value of 'post-classical' developments in analysis. Developments which made it possible to work on very small amounts of material were of particular value, partly because of the very expensive nature of many modern drugs, and also because of their very high potency, which implied that only small amounts would be present in many preparations. For a number of drugs (adrenaline, atropine, carbachol, vitamin B_{12}, digoxin, ergometrine, stilbœstrol and physostigmine being among the examples quoted) the human dose was only a fraction of a milligram.

Classifying these techniques into microchemical and microbiological, Dr. Foster defined microchemistry as "ordinary chemistry carried out on a small scale", and often with the aid of special instruments. Among these, the microbalance had its place; but it should be remembered that colorimetric methods—whether for actual assay of such drugs as morphine, ergot alkaloids or tubocurarine, or for the estimation of impurities such as trace metals—were also essentially microchemical in nature. The use of the photoelectric spectrophotometer in comparing colours of solutions, reducing error to about ± 0·1 per cent as compared with about ± 5·0 per cent in visual comparisons, was given as an illustration of the improved sensitivity which instruments could achieve.

Of microbiological assays, Dr. Foster said these had made their way into very wide and intensive use, calling as they did for little more than standard bacteriological technique and equipment, while effecting great savings of time and expense as compared with experiments on larger animals. Moreover, they could fill the gap when suitable larger subjects were simply unobtainable. Progress in research on the active agents in liver extract had been extremely slow so long as the only subjects known to be suitable for assay were human sufferers from pernicious anæmia. The development of methods measuring the potency of the extracts as growth stimulants for *Lactobacillus* species contributed largely to the identification of folic acid and vitamin B_{12}, while at the same time providing an effective assay.

Microbiological assays were of use for the control of both growth inhibitors (antibiotics and bacteriostatics) and growth promoters (vitamins, etc.). The principles of assessment of the amount of microbial growth from the turbidity of the culture, or from the diameter of the zone of growth promoted or inhibited by diffusion around a spot of the active agent on an inoculated agar plate, were equally useful in either context. For growth inhibitors, serial dilution in order to arrive at the minimal effective dose was also a practical alternative; while for growth promoters, titration of acid liberated in the metabolism of the growing organisms was often the most effective measure of growth.

Successful application of any analytical technique was largely dependent on preliminary isolation of the ingredient sought. In this connexion, Dr. Foster reviewed the group of varied procedures to which the name of 'chromatography' is customarily, though not very perspicuously, applied. Of these, the most universally serviceable is no doubt the solvent partition technique, with paper chromatography as its most usual adaptation. Counter-current solvent extraction, however, might logically be classed as an extreme modification of the same principle. Paper chromatography had been successfully applied in the study of the digitalis glycosides, the identification of the polymixins, the fractionation of liver extract, the separation of the penicillins, and the establishment of the molecular structure of insulin.

Adsorption and ion-exchange chromatography had had more limited though still extensive pharmaceutical uses, especially for isolation of vitamins (for example, D_2 and B_1) before colorimetric determination. Gas–liquid, also known as gas or vapour-phase chromatography, was the most recent arrival, but might well replace analytical distillation, especially for very small amounts of material. It had already been applied to the detection of impurities in Chloroform B.P., and the examination of essential oils seemed an obvious further application.

FORM AND FUNCTION IN THE MOLLUSCA

DURING the meetings of the British Association in Glasgow a session on "Aspects of the Evolution of Form and Function in Molluscs" was held in Section D, those delivering papers being all of them members of the Department of Zoology in the University of Glasgow. In his preliminary remarks, Prof. C. M. Yonge directed attention to the unique features of the Mollusca. The body is primitively bilaterally symmetrical with an antero-posterior axis of growth but over this extends a mantle, attached to the visceral mass and secreting a protective shell, which is initially biradially symmetrical growing by marginal increment. While such conditions continue to exist in the recently discovered monoplacophoran *Neopilina* and in a modified condition (by subdivision or by loss of the shell) in Polyplacophora and Aplacophora, evolution within the Gastropoda, Bivalvia and Cephalopoda represents interaction between the body, essentially head and foot, on one hand, and the mantle and shell on the other. In the Gastropoda a balanced condition often exists, but the mantle may dominate as in the sessile vermetids or it may diminish and disappear as in the opisthobranchs; in the Bivalvia the mantle completely encloses the body and is entirely responsible for external form, so largely controlling habit.

The respiratory chamber of the Mollusca consists of a primitively posterior mantle cavity containing the characteristic gills, paired ctenidia which consist of an axis containing afferent and efferent blood vessels, a branchial nerve and muscles, with rows of filaments alternately disposed on the two sides. Lateral cilia on the filaments set up a respiratory current which flows upward between the filaments within which blood flows in the opposite direction. Supporting rods within the filaments prevent buckling of the delicate tissues; cleansing cilia on marginal surfaces remove particles carried in suspension by the respiratory current.

No organs in the animal kingdom have been more successful or proved more adaptable[1]. With folding of the filamental surfaces and creation of a more powerful respiratory current by pulsations of the funnel and then of the mantle wall, these ctenidia cope with the oxygen needs of modern dibranchiate cephalopods, while with filaments greatly increased in numbers and in individual length they have become organs of feeding in the bivalve Mollusca, the most successful group of ciliary feeders. In the Gastropoda the effect of torsion has been to bring them to the anterior end, and that of asymmetrical coiling of the shell with loss of the marginal slit or apical aperture has been the reduction and loss of the right (post-torsional) ctenidium. In the Mesogastropoda reduction to a single (right) row of filaments on the left ctenidium occurs, but with enhanced efficiency. In the pulmonates the ctenidium is lost but the possibilities inherent in a mantle cavity with vascular walls become apparent, this forming a lung and being possibly the most important factor in colonization of the land and also of freshwaters by Gastropoda.

In the evolution of the Bivalvia[2] the original dome-like shell must have extended marginally and been laterally compressed. The mantle also became attached near to the margin of the shell. The final stage of compression was made possible by reduction of calcification along the mid-line dorsally while at each end there was cross-fusion of the pallial attachments to the shell in the regions of bending. There thus came into simultaneous existence the ligament and the two adductors, the means of opening and of closing the bivalve shell. Complete enclosure of the body by mantle and shell was accompanied by reduction and final loss of the head, feeding being probably taken over by mobile extensions of the lips, the palp proboscides, as in existing protobranchs, for example, *Nucula*[3]. The ctenidia remained primarily concerned with respiration, but further change produced the filibranch and eulamellibranch ctenidia, which collected food, the function of selection being retained by the palp lamellæ. The sensory functions of the head were taken over by the mantle margins, which consisted of an outer lobe concerned with the primitive function of secretion, a sensory middle lobe bearing tentacles and sometimes, as in *Pecten*, eyes, and an inner muscular lobe which controls the volume and site of the inhalant water current. Fusion of the mantle margins[4], to varying extent but initially always by the inner lobes, led to enclosure of the animal and to the formation of siphons enabling bivalves to burrow or bore deeply and yet retain contact with the water for food and oxygen. By the same means the primary ligament—of inner and outer layers with superficial periostracum—could be extended by secondary formation of a fusion layer representing union of the outer surface of the outer lobe of the mantle margins and particularly well shown in the long secondary extension of the ligament posteriorly in *Pinna*[5].

Following up this theme, G. Owen pointed out that the bivalve shell consists of two valves with a connecting ligament, not of two discrete valves united by a ligament of different origin. He noted that the description, as given by D'Arcy Thompson in "Growth and Form", of the growth lines of each valve as a system of closed co-axial lines is incorrect because the growth lines of the two valves are continuous across the primary ligament. Within the shell, loss of the head has the effect of reducing the anterior portion of the body so that in a simple dimyarian bivalve, such as the modern *Glycymeris*, a line drawn from the mid-point of the body dorsally through the middle of the foot divides the animal into almost equal anterior and posterior regions. This line may be designated the 'median axis'. Corresponding division of the mantle and shell is made by way of a line which, starting at the umbones, follows the zone of greatest convexity which in *Glycymeris* leads it to about the mid-point marginally. This demarcation line may be said to separate the mantle and shell into anterior and posterior territories; when projected on to a plane surface it corresponds almost exactly with the median axis of the body.

The form of the shell of a bivalve[6], neglecting here differences between the valves, depends on the growth gradients around the margin of the mantle. If greatest around the mid-point ventrally a symmetrical equilateral shell is formed as in *Glycymeris*. Where growth is greatest posteriorly the shell becomes elongated as in the razor shells (Solenidae)[7,8]. In these the demarcation line is close to the anterior end, the posterior territory being many times the area of the anterior, but the proportions of the body are *not* affected; although by influence of the form of the mantle and shell now bent into a U, the median axis continues to separate approximately equal anterior and posterior regions. The overall effect is formation of a cylindrical shell with short siphons posteriorly and an elongated foot emerging at the anterior end. This makes possible rapid vertical movements by which these bivalves escape danger from predators or from desiccation.

Elongation caused by centres of growth at each end of the mantle produces, by convergence, deep burrowers such as *Mya* (Myacea), *Lutraria* (Mactracea), *Panope* (Saxacavacea) and *Glauconome* (Veneracea)[8]. In all, the median axis and the demarcation line are little altered but there is great elongation of the fused siphons and great reduction of the foot. These animals are immobile deep burrowers reacting to danger solely by withdrawal of the siphons. A final example may be taken from the Tellinacea where, particularly in *Donax*, there is a tendency for enlargement of the anterior territory while, in correlation with the deposit feeding habit (in distinction to the other genera which are all suspension feeders), the animals have both long separated siphons and a powerful foot which enables them to move horizontally within the substratum.

These represent a few instances in which alterations in the form of the mantle and shell influence that of the body with notable effects on habit. Although impossible to discuss here, the opposite condition may occur with changes in the form of the body (probably always initially associated with byssal fixation) affecting that of the mantle and shell[2].

In his communication, Dr. G. E. Beedham directed initial attention to the fact that the ligament and the valves consist of the same three layers formed by the same means, (1) a superficial horny periostracum secreted by the inner surface of the outer mantle lobe and appearing to issue from a 'periostracal groove' between the outer and middle lobes, (2) an outer calcareous (or ligament) layer formed by the outer surface of the outer mantle lobes and (3) an inner calcareous layer formed by the general inner surface of the mantle, this being modified along the mid-dorsal line to constitute the mantle isthmus which secretes the inner ligament layer[9]. These findings he showed to be strengthened by study of the composition of the non-calcareous material (conchiolin) in the shell of *Anodonta cygnea*[10]. The chemical and histochemical properties of the outer layers of the valves and ligament are very similar. The conchiolin from both regions, and also that of the periostracum and the fusion layer of the ligament with which it is comparable chemically, consist principally of a quinone-tanned protein. Acid hydrolysates of this protein were analysed by paper chromatography and found to be rich in phenolic amino-acids, especially tyrosine, and in glycine.

The conchiolin components of the inner shell layers present a contrast. Hydrolysates contain appreciably more aspartic acid and glutamic acid, but much smaller amounts of tyrosine and glycine. Their protein constituents show only slight signs of tanning. In these properties, the inner layers of the valves and ligament appear basically alike. However, each component has certain peculiar features; acid hydrolysates of the inner ligament layer, for example, are characterized by a high content of proline and of the sulphur-containing amino-acid, methionine. These modifications in the protein of the inner ligament may well be correlated with the highly specialized function of this region of the shell.

The divergence in composition between corresponding layers of the valves and ligament may become more extreme in other bivalves. In *Ostrea edulis* and *Mytilus edulis* the outer layers of the valves and ligament each exhibit progressively greater specialization compared with the situation in *Anodonta*. This is most marked in *Mytilus*, where the conchiolin in the outer calcareous layer of the valves has almost the same composition as that in the inner layer, and consequently differs completely in character from that in the outer ligament layer. Nevertheless, in both these bivalves, the inner layers of the shell exhibit properties comparable with those of their counterparts in *Anodonta,* similarity between the inner ligament layers being particularly close.

In considering the evolution of Gastropoda in fresh waters, an account was given by Dr. W. Russell Hunter of work largely carried out at the field station maintained on Loch Lomond by the Zoology Department of the University of Glasgow. The snails of fresh waters are either prosobranchs, retaining the typical molluscan ctenidium and closely related to marine gill-breathing forms, or pulmonates with no ctenidium and the mantle cavity modified as a 'lung'. In both groups different degrees of adaptation to life in fresh waters co-exist, forming functional and morphological series. The ecological and physiological work reported upon was largely concerned with certain species of pulmonate snails, including *Lymnaea peregra, Physa fontinalis* and *Planorbis albus.* Some populations of these snails have to migrate periodically to the surface of the water to breathe[11]. Other populations of the same species can live in deeper offshore water, and a variety of conditions are found in their mantle cavities. In some the 'lung' is water-filled, the snails respiring by some other means, while in others it contains a gas-bubble, which may be used to obtain dissolved oxygen from the water, or merely to give buoyancy[12]. Similar variations between different populations within each species of snail are found in their reproduction: the breeding periods, the numbers of eggs produced, and the survival of the young vary from one population to another. Adaptive plasticity in their methods of breathing, feeding and reproduction is characteristic of freshwater molluscs as a whole. The process of evolution in animals like snails living in fresh waters has been markedly different from evolution in similar animals living in the sea or on land[13]. Freshwater environments are characterized by the high degree of small-scale, short-term isolation which can occur within them. Thus, it seems likely that both the adaptive plasticity found in several aspects of the physiology of freshwater snails, and the co-existence of different degrees of adaptation to limnic life, are associated with the discontinuity in space and the impermanence in time of most fresh waters[13].

A. E. Henderson described his experimental work on the mantle cavity mainly of the larger freshwater pulmonates, *Lymnaea stagnalis* and *Planorbarius corneus.* The use of the 'lung' as an air store for respiratory purposes during submergence has been at least partially supplanted by other functions. Some snails undoubtedly bring the gas-bubble in the cavity into contact with the water during submergence, and can extract sufficient oxygen by diffusional processes to prolong the period of submergence. But other animals, even of the same species, do not do this, and in such cases (perhaps in all) the hydrostatic function of the gas-filled cavity may dominate in determining the behaviour of the animal. In these larger species, the time taken for the bubble to be used up (by the extraction of oxygen to the point where the snail loses its buoyancy) is of the same order as the normal duration of a dive, suggesting that loss of buoyancy may determine the frequency of surfacing. Further, the loss of buoyancy caused by pressure at depth, and the fact that the snails are not found with gas in their cavities at just those depths where they lose their buoyancy, seems to indicate that the hydrostatic can be more important than the respiratory function in some species.

TIME-SPAN OF DISCRETION IN JOB ANALYSIS

A BOOK by Dr. Elliott Jaques* described a new approach to problems of payment for work involving, among other things, a new way of analysing the work content of roles and a suggested means of measuring responsibility. For the past eighteen months, J. M. M. Hill has been engaged in examining some of the concepts put forward in this book, in testing their validity, and in recommending if and how they should be used for the solution of problems experienced by the Glacier Metal Company, of which he is the policy research officer. In a recent paper† he describes some of the preliminary results of his examination.

The kernel of Jaques's approach may be described as follows. The work activities (or duties) which, under normal conditions of industrial contract employment, a man performs in return for pay may be divided into those that are prescribed (laid down for him so that he has no authorized choice in the matter) and those that are discretionary (in that judgment or the making of choices is called for from him). All jobs—even the most apparently 'routine'—call for some exercise in discretion, and no discretion is allowed to continue indefinitely without being subject to review by a superior. Jobs differ in the maximum length of time that discretion will be allowed to continue before a review takes place, and this maximum length of time—the time-span of discretion—is of fundamental theoretical and practical importance.

---

* "Measurement of Responsibility" (Tavistock Publications, Ltd., 1956).

† Tavistock Pamphlets No. 1: The Time-Span of Discretion in Job Analysis. By J. M. M. Hill. Pp. 29. (Reprinted from *Human Relations*, Vol. 9, No. 3.) (London: Tavistock Publications, Ltd., 1958.) 3*s.* 6*d.* net.

The time-span of discretion is a measure of level of work and of responsibility. That time-span of discretion is related to salary, inasmuch as there exists an ascending scale of monetary salaries corresponding to ascending time-spans of discretion. An individual doing a job in industry may be receiving remuneration at, above or below the level appropriate to the time-span of discretion of the job in question. Each of these three possibilities will be associated with different characteristics as regards the satisfaction and behaviour of those concerned. In particular, payment at the appropriate level will be experienced by the individual as satisfactory—he will not actively press for increase and will not express disruptive disaffection.

If Dr. Jaques's hypothesis is correct, it is a matter of fundamental importance to industry and may even provide a basis on which the apparently intractable problems of differentials may be settled. Before such notions and other economic implications of the idea may be investigated, Dr. Jaques's findings must be checked by observation and experiment and the actual time-span of discretion of jobs must be determined.

In the course of his work, Mr. Hill has been concerned with assessing the time-span of jobs and with the communication of the means of such assessment. In his paper the dependence of the existence of a clear time-span of discretion of a job on the existence of a clearly structured work situation is described, and some of the implications of this examined. Problems of assessing time-span in situations of unclarity are also discussed. The meaning of the term discretion is then described, expanded and exemplified, and reference made to some of the difficulties that may be met in discovering the discretionary aspects of a job. A review mechanism is then defined as any systematic means by which a manager becomes aware of the quality of his subordinates' use of discretion, and this definition is expanded and exemplified. Three kinds of review mechanisms discovered are described as:

Direct review, in which a subordinate hands back a completed piece of work to his manager for full inspection.

Indirect positive review, in which a manager deliberately seeks information about the way in which his subordinate has been using discretion, from sources outside that subordinate's control.

Indirect negative review, in which a manager relies on the fact that he will hear of the matter should his subordinate use discretion inadequately.

Jobs are then grouped as 'single aspect' or 'multiple aspect' according to whether only one or many different kinds of work activities are carried out. The boundaries between the different aspects of a multiple-aspect job are termed either 'permeable' or 'impermeable' according to the extent to which a review of discretion in one aspect leads to review of other aspects.

Within the framework given, a job may be set up in reality with a range of possible time-spans of discretion, and that within discoverable limits managers have choice concerning the time-span of discretion that they will allow a subordinate.

A description is also given of the means by which information about jobs may be elicited in order that the time-span of discretion may be assessed. Three examples of time-span analysis are presented and discussed. In each case the analysis concerns a particular kind of work, namely—the work of a draughtsman, a manual operator's work, and research work.

In future papers it is hoped to present an analysis of line management jobs, to examine the relationship of time-span with salary, to describe the use of the time-span instrument for organizational design, and to examine the implications that the use of such an instrument has for personnel management and for work study in industry.

EVIDENCE FOR PERMEABILITY MINIMA IN LOW-PRESSURE GAS FLOW THROUGH POROUS MEDIA

By Dr. D. M. GROVE and M. G. FORD

Queen Mary College, University of London, Mile End Road, London, E.1

FOR a gas flowing in a porous medium at a pressure such that λ, the mean free path of the gas molecules, is much less than $2r$, the mean pore diameter, it is well established[1] that there is a linear relationship between K, the permeability (cm.²/sec.), and $\bar{p}$, the mean pressure of the gas in the porous medium. Among the various equations put forward to represent such flow is that developed from the Kozeny equation by Carman and Arnell[2,3], which may be written as:

$$K = \frac{\varepsilon^3 \bar{p}}{k\eta A^2} + \frac{8}{3}\frac{\delta\varepsilon^2}{k'A}\sqrt{\frac{2RT}{\pi M}} \qquad (1)$$

where ε = porosity (cm.³/cm.³) of the porous medium; A = specific surface area (cm.²/cm.³) of the porous medium; k = Kozeny constant (5·0); k' = shape factor (2·0 to 2·5 for most porous media); η = viscosity of the gas; M = molecular weight of the gas; and δ = a coefficient of the order of unity.

All equations for slip flow are of the form[4]:

$$K = K_p\bar{p} + \delta K_k \qquad (2)$$

where K_p is the Poiseuille (viscous) flow and K_k is the contribution due to slip of the gas molecules at the pore walls[5]. The slip term is of the same form as the expression for Knudsen (molecular) flow, which for a porous medium may be written as[6]:

$$K_k = \frac{8}{3}\frac{\varepsilon^2}{A}\sqrt{\frac{2RT}{\pi M}} \qquad (3)$$

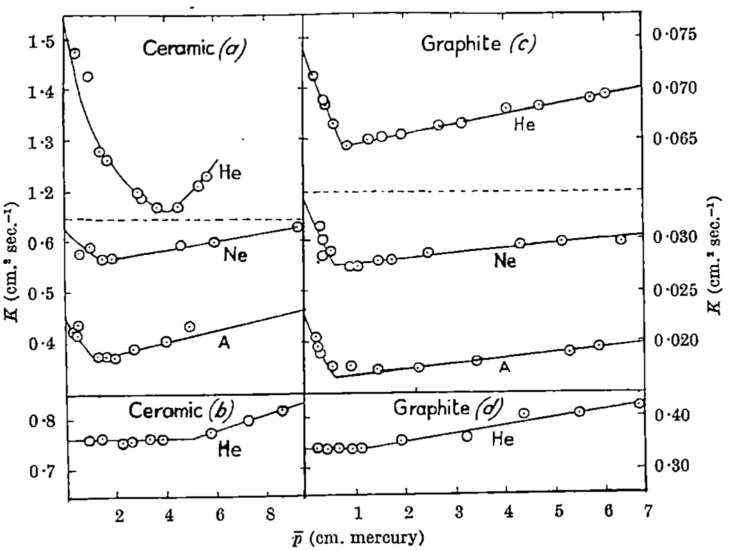

Fig. 1. Flow of inert gases at 25° C. through porous ceramics and through graphites

where the mean hydraulic radius $m = r/2$ is replaced by ε/A, assuming that the porous medium consists of uniform capillaries. An additional factor ε is introduced because flow occurs only in the pores and not through the entire cross-section.

At low pressures, when $\lambda \gg 2r$, viscous flow gives place to molecular streaming, the permeability K becomes independent of the mean pressure $\bar{p}$, in accordance with equation (3). A flattening of the permeability curve at low pressures has been observed by several workers[7,8]. Conversely, for materials having extremely fine pores, there may be no measurable Poiseuille contribution even at pressures of half an atmosphere[9,10]. Considerable discussion[11] has taken place concerning the numerical constants of K_p and K_k, including the shape factors k and k', and various values have been given to the coefficient δ, which appears to alter both with the mean pressure of the gas and with the material of the capillaries.

Gas flow in a single capillary also gives a linear relationship between K and $\bar{p}$ in the region of slip flow, but instead of the flattening at low pressures, a minimum is observed[12–14] in the permeability curve. More recently, Huggill[15] has obtained indications of such a minimum using a block of 1,400 capillaries of polymerized methyl methacrylate. Only a few tentative claims[16,17] have been made for permeability minima in porous media. Pollard and Present[18] have shown theoretically that a minimum is not, in fact, to be expected, since mean free paths much greater than the pore diameter will not occur in the tortuous and irregular capillaries of a porous medium.

Using consolidated porous media, we have now obtained several examples of quite marked permeability minima, some of which are shown in Fig. 1. The curves (*a*) for the inert gases flowing through a porous ceramic were the first we obtained of this type; the curves (*c*) for a relatively impermeable graphite are examples of the higher degree of accuracy obtained more recently. The existence of a minimum cannot be solely a property of the material of the porous medium, since (*b*) and (*d*), which are curves for other grades of ceramic and graphite, respectively, show a flattening at low pressures instead of a minimum. Nor does the minimum depend in a simple way on the mean pore radius calculated from the slope of the linear portion of the permeability curve. Table 1 gives the porosity ε determined by density measurements or helium displacement. This has then been used to calculate the mean pore radius, $r = 2\varepsilon/A$, and the specific surface area A from the first term in equation (1).

The results suggest that pore size distribution, rather than the mean pore radius, may be the factor which determines whether or not a minimum is observed.

Preliminary measurements of the surface areas of the ceramic and graphite samples by the standard Brunauer–Emmett–Teller method give in each case results between five and seven times greater than the values of A shown above. It is to be expected that permeability measurements will give a lower result since gas flow will occur mainly through the large pores and any blind pores will not take part, whereas the small pores, whether blind or not, will make a relatively greater contribution to the Brunauer–Emmett–Teller surface area[9].

Table 1

Porous medium	ε (cm.^{3}/cm.^{3})	$r \times 10^4$ (cm.)	A (cm.^{2}/cm.^{3})
Ceramic (*a*)	0·442	0·91	9,760
Ceramic (*b*)	0·280	1·30	4,320
Graphite (*c*)	0·183	0·348	10,520
Graphite (*d*)	0·174	1·61	2,160

The mean pressure corresponding to the minimum varies with the gas used, but for each sample the mean free path of the gas molecules is approximately constant at that pressure. For the ceramic (*a*) it is about seven times the mean pore radius, and this agrees with the results of Knudsen[12] and others for a single capillary, for which the ratio λ/r at the minimum is about 10. For the graphite (*c*), however, the ratio is 50. It is interesting to note that both for ceramic (*b*) and graphite (*d*) the end of the flat portion of the permeability curve corresponds closely to the position of the minimum for other grades of the same material, although the pore radii of the two graphite samples differ so widely.

This work will be published and discussed in more detail elsewhere.

CONDENSATION PRODUCED BY ULTRA-VIOLET LIGHT

By Dr. A. J. BARNARD and W. L. MOUTON
Physics Department, University of Natal, Pietermaritzburg, South Africa

IT was discovered by Lenard and Wolff[1] that the exposure of a damp gas in a cloud chamber to ultra-violet light may result in a marked increase in the condensation on expansion. Their experiments indicate that the ultra-violet light (although of too long wave-length to cause ionization) may form some kind of uncharged condensation nuclei. C. T. R. Wilson[2] investigated the effect in air saturated with water vapour, and ascribed it to the formation of hydrogen peroxide. He reported, however, that an increase in condensation could also be observed when the air was replaced by carbon dioxide or by hydrogen. More recently, Crane and Halpern[3] observed the effect in a conventional cloud chamber with an air – ethyl alcohol filling, and they attributed it to the formation of atomic oxygen. This theory was supported by Farley[4], who investigated the condensation of water vapour in a rubber-diaphragm cloud chamber. McHenry and Twomey[5], on the other hand, attributed the increased condensation observed with water vapour to the presence of an ammonia contamination in the air. It is evident that there still exists considerable doubt as to which component of the gas – vapour mixture is responsible for the effect. The present investigation was therefore undertaken with the object of ascertaining the origin of the condensation nuclei.

The initial experiments were performed with various gas – vapour mixtures in a conventional rubber-diaphragm cloud chamber. Light from a mercury discharge lamp equipped with a quartz lens was brought to a focus inside the chamber through a quartz window. At an expansion ratio normally just sufficient for the onset of spontaneous condensation, prior exposure to ultra-violet light produced a dense cloud. In these and in the subsequent experiments every fast expansion was always followed by a series of slow expansions to clear the chamber. The effect was studied using water as condensant and the following permanent gases in turn: room air; cylinder oxygen, nitrogen and argon; and, finally, cylinder nitrogen and argon which had been passed over heated copper to remove residual oxygen. No significant differences in the condensation could be seen with the different gases; such differences as were observed could always be explained in terms of the different rates of diffusion of the nuclei through the gases and/or the different ratios of the specific heats of the gases. It was noticed, however, that for a particular filling the density of the cloud due to ultra-violet irradiation increased markedly with time, attaining an equilibrium value after a few days. A similar effect was noticed when using ethyl alcohol as condensant. These experiments indicate that the nuclei do not arise from the permanent gas, but from a contamination given off by the chamber materials (probably by the rubber diaphragm).

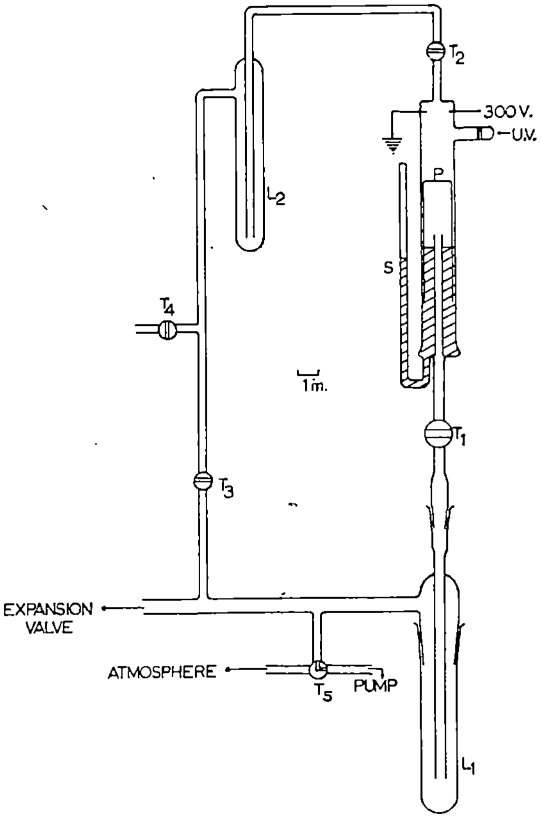

Fig. 1

To check this conclusion the chamber illustrated in Fig. 1 was constructed, and operated with water as condensant. In this chamber only glass, quartz, water and tap grease ('Apiezon *L*') came in direct contact with the working volume. (The tap T_2 could not be eliminated since preliminary experiments revealed that in sealing off a 'Pyrex' tube numerous nuclei are produced on irradiation.) All gases admitted to the chamber, either during the filling process or the operation of the chamber, first passed through the traps L_1 or L_2 surrounded by liquid air (or solid carbon dioxide). Ultra-violet light was admitted through the quartz tube Q fused to the chamber via a graded seal. To make an expansion, the space underneath the piston P was suddenly connected to a partially evacuated vessel through a magnetically controlled valve (the tap T_1 being open). The expansion ratio was controlled by adjusting the pressure in the partially evacuated vessel.

Before using the chamber, the tube above T_2 was broken, the chamber removed and washed out with a 1 : 1 mixture of concentrated sulphuric and concentrated nitric acid. Steam generated in an all-glass apparatus was then passed through the chamber for

15 hr. The distilled water used as condensant was prepared by the method recommended by Faure *et al.*[6]. De-ionized water was distilled from a mixture of potassium permanganate and sodium hydroxide and then directly into the chamber from phosphoric acid. A tin condenser was used in the final stage to avoid the impurities dissolved by water when condensing on glass. After filling, the taps T_1 and T_2 were closed, the chamber replaced and the tube above T_2 again sealed to the rest of the apparatus. To fill the chamber with clean gas, the taps T_1, T_2 and T_3 were opened and the apparatus slowly evacuated through T_5. The taps T_1 and T_5 were then closed and the gas admitted through T_4. This process was repeated a few times. Finally, the tap T_1 was closed, and the chamber pumped out slowly through T_2 until the piston rose to the desired height.

A 125-W. high-pressure mercury-discharge lamp was used in conjunction with this chamber, and the drops could readily be observed in its light. Expansions were made at the same ratio alternately with and without a glass filter in the beam, and the number of drops estimated visually. (It was checked that the glass filter removed completely tho wave-lengths responsible for the nuclei.)

With room air as the permanent gas, exposure to ultra-violet light still caused the number of drops to increase by a factor of the order of 10. If, however, the air was first passed through phosphoric acid in a bead tower and then through the liquid air trap L_2, no increase in the condensation could be detected on exposure.

It can therefore be concluded that the vast majority of nuclei (if not all) usually observed with water vapour is due to some contamination. If any nuclei are formed with distilled water and purified air, the number is too small to be detected with our technique. So far as we can see, no particular care had been taken by previous workers to eliminate impurities, and these impurities could have given rise to the observed effects.

Wilson[2] also found that a cloud could be formed by merely irradiating damp air with an intense ultra-violet beam. His experiment was repeated using a glass vessel with a quartz tube fused to it via a graded seal. With distilled water and room air in the apparatus, no cloud could be seen even after irradiating for about 10 hr. When traces of impurities (such as carbon tetrachloride or ammonia) were introduced, however, a cloud formed after exposing for a few seconds. With pure carbon tetrachloride (fractionally distilled from a 10-ft. column containing stainless steel rings) a cloud of small drops could also be formed by irradiation only.

No explanation of the mechanism of the condensation process is attempted at this stage. Further investigation is necessary, and the work is being continued.

This investigation was started by one of us (A. J. B.) at the Department of Natural Philosophy, University of Glasgow. We wish to thank Prof. P. I. Dee and Mr. J. R. Atkinson for their interest and for helpful discussions.

DIRECT RECORDING OF FLUORESCENCE EXCITATION SPECTRA

By Dr. C. A. PARKER

Admiralty Materials Laboratory, Holton Heath, Poole, Dorset

THE use of absorption spectroscopy for the identification of unknown substances is limited to concentrations of 10^{-5} *M* or more, the measurement of a complete absorption spectrum at lower concentrations than this requiring an inconveniently long optical path. The measurement of fluorescence emission spectra as a means of identification at much lower concentrations is now becoming commonplace, but unfortunately the fluorescence emission spectrum alone is, in general, not so specific as the absorption spectrum because it corresponds to transitions only from the lowest excited state of the molecule, irrespective of the wave-length used for excitation. Previous work in this laboratory[1] has shown that the measurement of the fluorescence excitation spectrum provides a method of identification which is as specific as the absorption spectrum and can be made at far lower concentrations. It was suggested[1] that the 'true' fluorescence excitation spectrum should be defined as the fluorescence output (of a sufficiently dilute solution) measured as a function of the frequency of the exciting light at constant quantum intensity. Under these conditions the fluorescence output is proportional to the product of the fluorescence quantum yield, φ, and the extinction coefficient, ε, of the fluorescent substance, and for many substances where φ is independent of frequency, the excitation spectrum is identical with the absorption spectrum. It has the advantage over the absorption spectrum that it can be measured in the presence of other strongly absorbing substances provided that sufficiently dilute solutions are used. Weber and Teale[2] have recently also discussed these points. They have investigated the fluorescence excitation spectra of a variety of organic compounds in solution and report a list of twenty-six compounds for which the fluorescence quantum yield is constant over a wide range of wave-lengths. They have also described conditions under which the fluorescence yield may not be constant, and the useful conclusions which can be drawn from a comparison of the excitation and absorption spectrum of a pure substance.

It is unfortunate that most spectrofluorimeters record only the apparent excitation spectrum, that

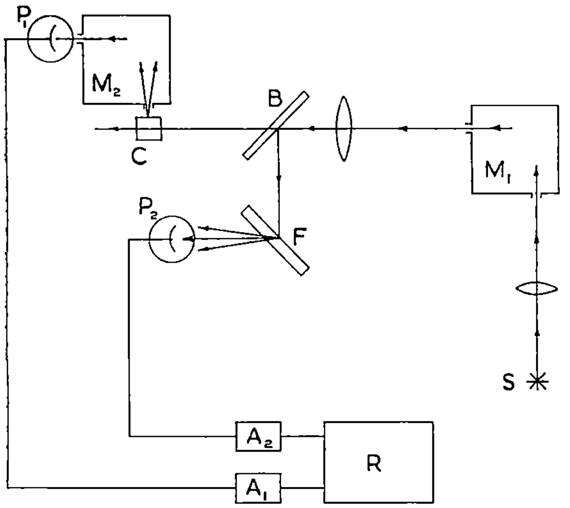

Fig. 1. Arrangement for recording true excitation spectra

is, the product $I\varphi\varepsilon$ versus frequency or wave-length, and since the intensity (I) available at the exit slit of the monochromator used to isolate the exciting light often varies considerably with frequency, the spectrum observed is seriously distorted and important features may be missed entirely. The true excitation spectrum can, of course, be calculated from the observed spectrum by measuring the spectral intensity of the light reaching the fluorimeter cell, but this calculation is time-consuming, particularly when a large number of experiments have to be made.

The value of the method in analytical chemistry would obviously be greatly increased if the true excitation spectrum (or a close approximation to it) could be directly recorded by the spectrofluorimeter. The arrangement shown in Fig. 1 has been designed for this purpose. The exciting light from the monochromator M_1 is focused on the sample in cell C, but a small proportion of the beam is reflected by the clear silica plate B on to the front surface of the fluorescent screen F. This consists of a silica cell, 5 mm. optical depth, containing a suitable fluorescent solution the fluorescence of which is viewed through the back face of the cell by the monitoring photomultiplier P_2. A suitable band of fluorescent light from the sample in C is selected by the monochromator M_2 and is received by the photomultiplier P_1. After amplification the outputs of P_1 and P_2 are passed to the ratio recorder R. The frequency drum on M_1 is motor driven, and as the frequency is varied the slits are adjusted so as to maintain the output of P_2 approximately constant (within a factor of 2). If the contents of F are suitably chosen, the output of P_2 can be made proportional to the quantum output of M_1 over a wide frequency-range. R then records the true fluorescence excitation spectrum of the sample in C.

Fluorescent solutions chosen for the monitoring cell F should ideally have constant fluorescence yield and absorb substantially the whole of the beam within a depth of about 1 mm. or less, over the whole spectrum-range concerned. Thus the fluorescent light has to penetrate a further 4 mm. of solution before reaching P_2 and this solution thus acts as a filter for the exciting light and at the same time ensures that substantially the same band of fluorescent light reaches P_2, irrespective of the depth of penetration of the incident beam[3]. In preliminary experiments a solution of $4 \cdot 4 \times 10^{-3}$ M fluorescein in a mixture of sodium carbonate and bicarbonate (both $0 \cdot 1$ N) was used. Although the fluorescence yield of this solution is not precisely constant[4] it was sufficiently so for these preliminary trials. The apparent relative fluorescence yield of this solution was determined by measuring the dose-rates of monochromatic ultraviolet light received by the contents of the cell, C, using the ferrioxalate actinometer[5] and comparing these with the corresponding readings of P_2. A Siemens xenon arc lamp type XC was used as a source of light with Hilger $D247$ quartz prism monochromators for M_1 and M_2. Rather large fluctuations in light intensity were observed, and a number of experiments were done at each wave-number setting of M_1. The mean results for the apparent relative efficiency of the monitoring screen (column 5 of Table 1) are accurate to about ± 5 per cent. They represent the correction which must be applied to the observed output of P_2 to obtain the relative intensity received by the contents of C. (They do not represent precisely the true relative fluorescence quantum yield of the contents of F owing to changes of reflectivity of the beam-splitter B and the transmission of the cells F and C.) The overall deviation from linearity is ± 10 per cent. This is adequate for many purposes without applying the correction. The linearity can no doubt be improved by choice of a more suitable solution for F. The range (which with fluorescein extends to below $2 \cdot 0\mu^{-1}$ before transmission becomes appreciable) can be extended to somewhat lower wave-numbers by the use of a solution of rhodamine B in ethylene glycol[6].

The excitation spectrum of 1 : 2-benzanthracene in ethanol recorded with the present apparatus is shown in Fig. 2 alongside the absorption spectrum as measured with a Unicam $SP500$ spectrophotometer. The excitation spectrum shows all the features of the absorption spectrum although it is not identical with it owing to the differing band-widths used. The excitation spectrum of a substance of biological interest, 5-hydroxytryptamine (present as the creatinine sulphate complex), is shown in Fig. 3 (curve 1). The fluorescence of this substance occurs entirely in the ultra-violet region (maximum at $2 \cdot 9\mu^{-1}$). The excitation spectrum is similar to the absorption spectrum and is clearly a much more useful record than the second curve which was recorded at constant slit width without the use of the fluorescent screen

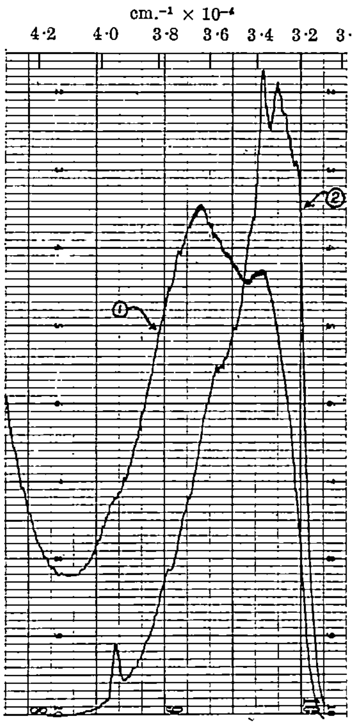

Fig. 3. 5-Hydroxytryptamine creatinine sulphate in water. Excitation spectrum recorded with (curve 1) and without (curve 2) the monitor. Fluorescence observed at 2·85–3·0μ^{-1}

monitor. Owing to the rapid change in the intensity of the exciting light with frequency the latter bears little resemblance to the absorption spectrum of the compound.

The present measurements were made using a monochromator for the isolation of both the exciting and fluorescent light. Owing to the comparatively narrow aperture of the monochromators, the intensity of the fluorescent light available at P_1, and hence also the overall sensitivity, was limited. The tests on 1 : 2-benzanthracene and 5-hydroxytryptamine shown in Figs. 2 and 3 were done with comparatively concentrated solutions ($10^{-6}\,M$ and $10^{-5}\,M$ respectively). Satisfactory spectra could be obtained with concentrations one hundred times less than these values although there was an inevitable increase in the noise-level on the curves, and the fluorescence 'blank' also became appreciable. For example, the excitation spectrum of 5-hydroxytryptamine is shown in Fig. 4 recorded at a concentration of $10^{-7}\,M$ (upper curve). The lower curve on this figure is the corresponding 'blank' obtained with pure water in the cell. Instrumental sensitivity can be increased considerably by the use of filters to isolate the fluorescence for P_1, but at the expense of some versatility and convenience. (The choice of secondary filters is sometimes very difficult with substances fluorescing in the ultra-violet region.) When working at very low concentration great care must be taken to avoid interference by fluorescence or scatter from solvent and by fluorescence of cell or secondary filters. It is, of course, always necessary to take measurements with pure solvent in the cell to determine the magnitude of the 'blank' excitation curve.

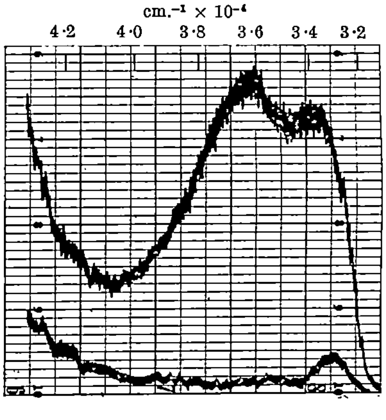

Fig. 4. Excitation spectrum at high sensitivity. Upper curve, $10^{-7}\,M$ 5-hydroxytryptamine creatinine sulphate in water; lower curve, water alone

I thank Dr. E. J. Bowen for much helpful discussion. I also wish to acknowledge the assistance rendered by Mr. C. G. Hatchard, who carried out the chemical actinometry.

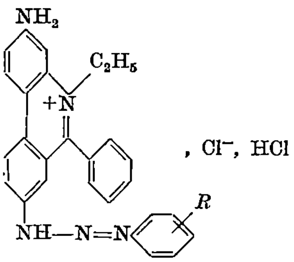
Metamidium: a New Trypanocidal Drug

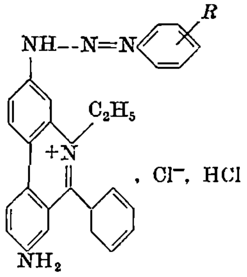
THIS communication describes a new trypanocide, which has been found to possess considerable potentiality as a curative and as a prophylactic drug, both in laboratory experiments and in field trials carried out in Africa during the past year.

In following up the long-standing interest in these laboratories in the trypanocidal activity of both phenanthridinium salts[1] and the aromatic diamidines[2], we decided to prepare the *p*-amidinophenyldiazoamino-derivative[3] of 2 : 7-diamino-10-ethyl-9-phenylphenanthridinium chloride (homidium chloride). The diazoamino linking group was selected because of the structural relationship our product would then bear to the recently introduced curative trypanocidal drug 'Berenil', *p*-amidinophenyldiazoamino-*p*-benzamidine[4].

The coupling reaction between diazotized *p*-aminobenzamidine (1 mol.) and homidium chloride in the presence of sodium acetate (7 mol.) at a temperature of 0–5° C. yields a mixture of two isomeric *p*-amidinophenyldiazoamino-derivatives, which can be separated by precipitation from water with sodium chloride, followed by fractional crystallizations from water and from methanol. The relatively water-insoluble isomer, m.p. 287–289° (dec.), was purple and the other, m.p. 236–240° (dec.), red. Both isomers were self-indicating on paper electrophoresis in 3 *N* acetic acid, the purple isomer being distinctly more mobile than the red; this provided an invaluable means of following the progress of separation procedures.



(I)



(II)

Since in 2 : 7-diamino-10-methyl-9-phenylphenanthridinium chloride (dimidium chloride) it is the 7-amino-group which reacts preferentially on acetylation[5], we provisionally assigned the structure (I; *R* = *p*-amidino) to the predominating purple isomer and (II; *R* = *p*-amidino) to the red isomer. Work to provide unambiguous proof of structure continues. A diazoamino structure was expected from the method of preparation and the expected microanalytical figures were obtained for both isomers. Infra-red spectra ruled out the remote possibility that the isomers were due to the existence of two stable tautomeric forms of the diazoamino-group in one or other of the structures (I) or (II). The presence of a diazoamino-group in each isomer was confirmed by the rapid evolution of nitrogen on boiling in 6 *N* sulphuric acid—the red isomer yielded nearly the theoretical volume of nitrogen, while the purple regularly yielded only about 65 per cent (the reason for this deficiency is at present unexplained).

The very promising results obtained on testing the isomers (I and II; *R* = *p*-amidino) as trypanocides led us to study extensively structure/activity relationships among similar pairs of isomers, particularly those in which the substituent *R* and the group in the phenanthridine-10 position were varied. As a result, we found that the most promising product was a mixture of the two isomers (I and II; *R* = *m*-amidino)[6], first designated M & B 4404, and later

Homidium chloride	0·025	1/10								
Berenil	0·06	0/10								

assigned the common name metamidium chloride hydrochloride.

In metamidium the two isomers are present in the same relative proportions (approximately 55 per cent purple isomer and 45 per cent red isomer; Campbell, H., and Muggleton, D. F., private communication) as are formed in the coupling reaction between diazotized *m*-amino-benzamidine and homidium chloride. Both isomers have been separated by methods similar to those described above for the *p*-amidino series, to give a purple isomer, m.p. 258–260° (dec.), and a red isomer, m.p. 244–245° (dec.), both in the form of their chloride hydrochloride salts. Metamidium chloride hydrochloride is 12·5 per cent w/v soluble in water at 25°, the *p*H of a 1 per cent solution being 6·65.

The suramin salt[7] of metamidium, designated M & B 4427, was precipitated and dried *in vacuo* at room temperature to give a dark purple powder, which was less than 20 μgm./ml. soluble in water at 20° C. For biological evaluation this solid was presented as a 10 per cent w/v ball-milled aqueous suspension.

The foregoing compounds were examined for activity against a laboratory strain of *Trypanosoma congolense* which gave an acute infection in mice. A single subcutaneous injection was administered to mice with an infection in the peripheral bloodstream of from 1–10 trypanosomes per high-power field. Ten mice were used for each dose, and five untreated controls which died within 5–7 days were included in each experiment. Homidium chloride was used as a standard.

Wet blood smears were examined three times a week for four weeks, and the number of animals clear of trypanosomes for that period (that is, cured) was noted for each dose. The *CD*50 (the dose which cured 50 per cent of the mice) was then obtained graphically for each compound using de Beer's method[8]. The subcutaneous *LD*50 for each compound was also obtained in mice.

The results of these therapeutic and toxicity experiments are given in Table 1, together with the results obtained with metamidium and homidium against two more recently isolated strains of *T. congolense*, which we obtained through the courtesy of the East Africa Trypanosomiasis Research Organization, Tororo, and the Veterinary Research Laboratory, Kabete. These experiments were carried out less than twelve months after the strains were isolated.

These results show that metamidium chloride hydrochloride was more active than homidium chloride against all three strains of *T. congolense.*

Prophylactic experiments in mice were also carried out with some of the compounds. In these experiments a single subcutaneous injection of the substance was given to a large batch of mice and groups of them were challenged intraperitoneally with approximately 65,000 *T. congolense* (laboratory strain) per mouse at various times after dosing. No mouse was challenged more than once.

The mice were examined for trypanosomes for four weeks after challenge, as in the therapeutic experiments, and those which remained clear of trypanosomes for this period were considered to have been protected. Untreated controls were infected at each challenge and these became positive for trypanosomes within five days.

The results of these experiments are given in Table 2.

Metamidium chloride hydrochloride completely protected mice for up to sixteen weeks at about one-ninth of the *LD*50. This was an interesting result because neither the parent compound, homidium chloride, nor the drug 'Berenil', with which metamidium shares some structural similarities, has any appreciable prophylactic activity at one-third of the *LD*50.

Of the two isomers of metamidium, the red was more active than the purple both therapeutically and prophylactically, but there was little difference in their toxicities.

We thank Dr. H. J. Barber and Dr. R. Wien for the constructive interest they have taken in this work.

A Rate-Governing Reaction of Protein Synthesis

RABBIT reticulocytes synthesize hæmoglobin *in vitro*. In order to maintain a high rate for at least four hours there needs to be added to the saline solution in which the cells are suspended a mixture of amino-acids, glucose, iron and an iron-chelating agent. The rate then (in four hours) is about five times that in saline alone. Glucose, iron and chelating agent have little effect on the rate unless the amino-acid mixture is added with them[1].

When in a reaction mixture complete except for one amino-acid, and that amino-acid is added in the carbon-14-labelled form and in varying concentration, the rate of its incorporation was found to vary as a first approximation with the concentration according to the equation $\frac{v}{V} = \frac{[A]}{[A] + K}$, where v is the observed rate at any given concentration, V is the maximum rate, $[A]$ is the concentration of the labelled amino-acid added to the reaction mixture and K is constant, which is formally identical with K_m in the Michaelis–Menten equation, that is to say, it is the equilibrium constant for the combination of substrate with enzyme. In the present instance $K = \frac{[B][A]}{[BA]}$, where B is a substance in the cells with which $[A]$ combines, and the rate of incorporation (fraction of the maximum) is proportional to $\frac{[BA]}{[B][BA]}$. The term $[BA]$ governs the rate of protein synthesis.

Table 1

Molar concentration of labelled leucine	Counts for 20 mgm. protein in 60 min.	Observed percentage of the maximum rate	Calculated percentage of the maximum rate for $K = 1 \cdot 25 \times 10^{-5}$
1×10^{-3}	3,369	100	100
5×10^{-4}	3,276	97	97
1×10^{-5}	1,608	47	44
5×10^{-6}	884	26	28
$2 \cdot 5 \times 10^{-6}$	598	17·7	16·6
$1 \cdot 0 \times 10^{-6}$	249	7·4	7·4
5×10^{-7}	107	3·2	2·4

Table 1 gives the results of a typical run. 0·25 ml. of packed reticulocytes was suspended in 32 ml. of a complete reaction mixture[1] except for labelled leucine, the concentration of which was varied. The temperature was 25° C., the incubation time 15 min. The proteins were washed and counted as previously described.

In different experiments the values of K varied over the range $0 \cdot 7 \times 10^{-5}$ to $1 \cdot 5 \times 10^{-5}$, but the variation within each run with concentration of leucine was according to the above equation. Preliminary experiments with labelled histidine, methionine and phenylalanine indicate that their minimum concentration for maximum incorporation was the same as that of leucine, namely, approximately 10^{-3} M, and also that their equilibrium constant was of the same order, namely, about 1×10^{-5}. The cause of the small variations from experiment to experiment needs to be understood before anything can be said regarding the value of K for different amino-acids. There may be a number of inter-related equilibrium reactions, and the value of K which is calculated would then be that for the overall equilibrium.

As there were maximum amounts of all the amino-acids needed except the labelled amino-acid the incorporation of which was measured, it follows that the hypothetical substance B, the combination of which with an amino-acid governs the rate of protein synthesis, is different for each amino-acid. These experiments do not tell what B is. Among the possibilities are that B is the locus of the amino-acid on the template or B is some specific carrier of the amino-acid.

Inhibition of Dextransucrase by Excess Substrate

HEHRE[1], working with the enzyme dextransucrase, showed that a plot of initial velocity v against substrate concentration deviated from linearity above a sucrose concentration of 200 mM. This was tentatively explained on the basis of a decrease in concentration of water in the stronger sucrose solutions.

Our interest in this polysaccharide-synthesizing enzyme[2] prompted us to examine this phenomenon more closely. Using fructose production as a measure of enzyme activity, the conversion of sucrose to dextran was examined in substrate concentrations ranging from 20 mM to 1,000 mM. The details of the enzyme preparation and the analytical procedure have been reported elsewhere[2]. A sucrose solution (1 ml.) containing 0·1 M acetic acid–sodium acetate buffer at pH 5·0 was added to the enzyme solution (0·2 ml.) and the mixture incubated at 30° C. in a constant-temperature water-bath for half an hour. The reaction was quenched at the conclusion of this time by the addition of 0·1 N sodium hydroxide (1 ml.) and the reducing sugars determined[3,4]. The results of these experiments are shown in Fig. 1.

Assuming that excess substrate inhibits this particular reaction, the following mechanism may be postulated[5] :

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E + P \tag{1}$$

$$ES + S \underset{k_5}{\overset{k_4}{\rightleftharpoons}} SES \tag{2}$$

$$K_{ss} = [ES][S]/[SES] \tag{3}$$

where E = enzyme, P = products, S = substrate, SES = inactive complex, K_{ss} = dissociation constant for inactive complex.

The steady-state treatment of the above mechanism yields the following rate equation :

$$\frac{S}{v} = \frac{K_m}{V} + \frac{S}{V} + \frac{S^2}{VK_{ss}} \tag{4}$$

where K_m = Michaelis constant, V = maximum initial velocity. Differentiating (4) with respect to S yields a linear relationship (5) between S and the tangent of the curve resulting from a plot of S/v against S.

$$\frac{\mathrm{d}(S/v)}{\mathrm{d}S} = \frac{1}{V} + \frac{2S}{VK_{ss}} \tag{5}$$

The values for K_m, K_{ss} and V may be readily calculated from the slope intercept relationships obtained from the plots of equations (4) and (5). Performing the necessary arithmetic we obtain the following values: K_m = 35 mM, V = 0·35 mgm. fructose/0·2 ml. enzyme/half an hour and K_{ss} = 3,900 mM. It will be noticed that the first two values agree closely with the values obtained previously[2] for these two constants. Substituting the derived figures for the three constants into equation (4) a calculated value for the initial velocity v may be obtained. This is shown by the smooth curve in Fig. 1.

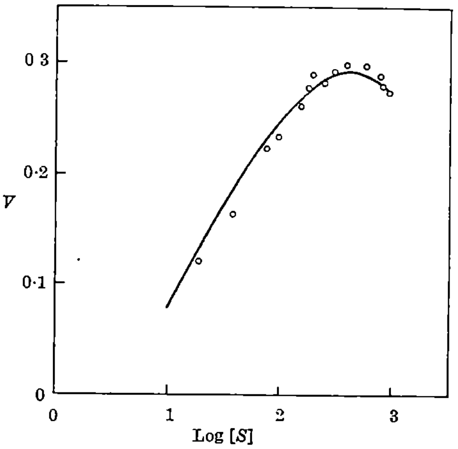

Fig. 1. Plot of initial velocity (mgm. fructose/0·2 ml. enzyme/½ hr.) against the logarithm of substrate concentration. The open circles represent experimental points while the smooth curve was calculated from equation (4)

The close correspondence between the experimental and the calculated curve tends to substantiate the original assumption that it is excess substrate which inhibits this particular enzyme. From the theory of the two-step reaction systems[5] another point of interest may be derived from the present work. If the enzyme has the same affinity for both the first and second substrate molecules, the value of the quotient $K_{ss}/4K_m$ will be unity. If the affinity is greater for the first substrate molecule, the ratio will be greater than unity. It is obvious that the second alternative holds in the present case, namely, that dextransucrase has a much greater affinity for the first substrate molecule than it does for the second.

Determination of the Mass Thickness of Cell Membranes from their Electron Micrographs

In this communication, we give values of the mass thicknesses of the cell membranes of *Bacterium coli*, human red blood corpuscle and *Leishmania donovani* estimated as follows.

Purified normal cells in each case were disrupted by chemical means to remove the cellular contents. The cell membranes, after separation, were collected on collodion-coated grids, and after drying only collapsed cell membranes remained. These were then examined with a Siemens 'Elmiskop I' electron microscope at 60 kV. with an objective aperture angle of $\sim 10^{-2}$ radian, and afterwards photographed on Ilford Process plates. After due processing of the plates, the photographic densities D_t and D_0 in the imaged region and in the background respectively were measured with a densitometer. For the photographic negative used, it was found from a previous experiment that the γ value under the above working and processing conditions was 2·8 within the photographic density-range 1·5–3·0.

Since in a photographic negative containing both the specimen and the supporting film regions, the time of exposure was the same, it followed that the respective measured densities D_0 and D_t were related to the corresponding electron intensities by the relation:

$$D_0 - D_t = 2{\cdot}8 \log_{10} (I_0/I_t) \qquad (1)$$

It is known from the electron scattering formula of Liesegang[1] that in the electron microscope the image intensity I_t is related to the object mass thickness ρx by the expression,

$$I_t = I_0 \exp\left(-\frac{N_A}{\pi} \cdot \frac{Z^{4/3}}{A} \cdot \lambda^2 \cdot \rho x\right) \qquad (2)$$

where the symbols have their usual meanings.

It has been shown by Zeitler and Bahr[2] that for various biological materials equation (2) can be written as:

$$I_t/I_0 = \exp(-4{\cdot}43 \times 10^4 \rho x) \qquad (3)$$

for 60 kV. electrons. Combining equations (1) and (3), ρx is given by:

$$\rho x = \frac{D_0 - D_t}{2{\cdot}8} \times 52{\cdot}4 \ \mu\text{gm.cm.}^{-2} \qquad (4)$$

The relevant data and the corresponding mass thicknesses of the cell membranes are given in Table 1.

Table 1. MASS THICKNESS OF CELL MEMBRANES

Specimen	Photographic density		Mass thickness of the cell membrane ρx (μgm.cm.$^{-2}$)	Computed thickness assuming $\rho = 1$
	D_t	D_0		
(Cell membrane) *Bacterium coli*	2·29	2·49	1·86	186 A.
Human red blood cells	1·58	1·85	2·51	251 A.
L. donovani	2·54	2·88	3·16	316 A.

The mass thickness of the cell membrane, as calculated from equation (4) with the help of the data in columns (2) and (3) above, is really the density multiplied by twice the membrane thickness, as the two membranes collapse together and provide the photographic density D_t. So the mass thickness of a single membrane of a cell would be half that of the value estimated from equation (4) and has been recorded in column (4).

Assuming the value of unity for ρ, the density of the material composing the membranes, the respective membrane thicknesses are as recorded in column 5. These values are to be compared with the thickness values of (100–150 A.), (120–300 A.) and 250 A. respectively reported by other workers[3-5].

Thanks are due to Prof. N. N. Das Gupta for his kind help and interest in this work and to Mrs. J. Chakraborty, and Messrs. S. B. Bhattacharjee and K. N. Bhattacharjee for their help in preparation of the specimens. Thanks are also due to the Ministry of Scientific Research and Cultural Affairs, Government of India, for financial assistance.

A New Method of tracking Artificial Earth Satellites

Existing instruments for making precise trajectory observations on artificial Earth satellites generally employ photographic techniques, a good example being the Schmidt–Baker–Nunn cameras of the Smithsonian Astrophysical Observatory. Since the launching of *Sputnik* 2, we have been experimenting with optical tracking by a photo-electric method which appears capable of adequate sensitivity and a precision comparable with that of astronomical observations, and thus high enough for observing the non-secular perturbations of a satellite orbit. The principal

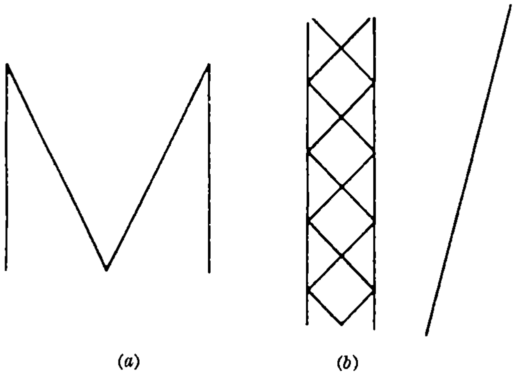

Fig. 1. Slit systems which can be used to determine the line of sight of a satellite: (a) the simplest system which has been used; (b) a version giving greater precision

advantage of the method is the simpler design of the optical system since a long focal length can be used, unlike the photographic method where a short-focus lens is required. The correction of lens aberrations is thereby rendered much easier. A performance in many ways comparable with the Schmidt–Baker–Nunn camera has been obtained with a lens having a 5-in. diameter aperture and 14-in. focal length.

The method used is as follows: A system of slits is placed in the focal plane of a lens and, behind them, a photo-multiplier. As the satellite, which must be sunlit, moves across the sky, its image moves across the slits and produces a series of pulses. These enable the position of the track in the sky to be determined if the orientation of the lens axis is also known. This can be found by stellar observations. If the azimuth and elevation of the satellite are expressed as power series in time of the nth degree, the minimum number of slits required is $(2n + 2)$. We have so far mainly used what is perhaps the simplest system possible, of the form shown in Fig. 1*a*. It is here necessary to assume that the apparent path of the satellite is a straight line, the satellite moving with constant angular velocity. The azimuth and elevation of two points on the track, spaced at a distance equal to the angular width of the slit system, are then found. The estimate of the angular velocity so obtained is of relatively poor precision unless widely-spaced slits are used, so the best method of making accurate measurements of angular velocity is to make a number of observations over a large part of the trajectory. The error caused by the assumption of a linear track can be reduced by making the slit system sufficiently narrow, but in order to cover a reasonably large part of the sky a rather more complicated slit system such as that shown in Fig. 1*b* must then be used. The extra slit is in this case used to identify the element of the system over which the track has passed.

The limiting satellite magnitude which can be detected is determined by the shot noise in the photomultiplier due to steady illumination of the slits by skylight and starlight, which generally exceeds the noise due to the dark current of the cell. When the bandwidth of the recording system is an optimum, the signal-to-noise ratio is proportional to $(\sigma A/B\omega\theta)^{1/2}$, where σ is the photocathode sensitivity, A the lens aperture area, B the sky brightness, ω the angular velocity of the satellite and θ the length of the slits. The width of the slits does not appear in this expression, so that the accuracy and sensitivity of the system can be adjusted independently.

The much lower angular velocity of stars makes possible discrimination against the signals they produce. The image of star or satellite is made just to fill the width of the slits, by defocusing if necessary, and the differentiating time constants of the recording system are then so chosen as to discriminate strongly against the slowly rising pulses produced by stars.

We have so far used two different telescopes, with apertures of 2 and 5 in. The peak noise-level of the larger instrument, produced by the midnight sky in July, is equal to the signal from a 10th magnitude object. Each instrument has a precision of about 15 sec. of arc, but different methods of calibration with stars are used. On the 2-in. telescope, the photocell must be removed and replaced by a photographic film. The slits are so constructed that a large area of sky around them can be photographed to obtain the orientation of the axis. The other telescope is fitted with accurate scales of azimuth and elevation which are calibrated by allowing stars to trail across the slits (the time constants of the recording system being adjusted to allow this). The accuracy of the first instrument is limited by the optical system, that of the second, on which the centre of the image can be located to 2 sec. of arc, by the mechanical construction.

No reason is apparent why a suitably designed optical system should not give a very substantially higher accuracy than these telescopes. A rather larger aperture is also easily obtained and would give a useful improvement in sensitivity. We now propose to build such equipment, and to exploit more fully the potentialities of this method.

The signal-to-noise ratios we have observed indicate that objects as bright as *Sputnik* 3 could be detected by this method during the daytime, using a field of view of about ½°. We have not yet attempted to do this.

A record obtained on July 23 from the rocket of *Sputnik* 3 with the 5-in. telescope is reproduced in Fig. 2. Five successive passages of the satellite across the slits were recorded, the telescope having been moved progressively across the sky. There are some additional pulses on the record which occurred when the telescope was being moved. The slit system was a simplified form of that shown in Fig. 1*b*, so that a fifth pulse occurs on some sets. The marked variation of brilliance of the satellite is clearly shown. The timing marks are 1 c./s. pulses from a chronometer. This record can be measured to an accuracy equivalent to 1 min. of arc. During this phase of the work we used a low recorder speed with a consequent loss of timing accuracy. We are now using recorder speeds more consonant with the accuracy of the optical system. Figs. 3*a* and 3*b* show the two telescopes.

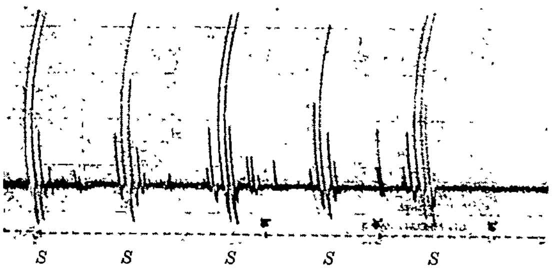

Fig. 2. A record of *Sputnik* 3 rocket. The groups of pulses marked *S* are due to the satellite, the remainder having been produced as the telescope was moved

Scale Height of the Upper Atmosphere

Several formulæ have been published recently for calculating the effect of air resistance on orbits of artificial Earth satellites. The latest and most complete are by King-Hele and Leslie[1]. Nearly all these formulæ are valid over a somewhat limited range of eccentricity and are based on a spherical Earth. The effect of ellipticity is by no means negligible and can be corrected for without much additional complication.

If the scale height of a homogeneous isothermal atmosphere is H at a distance r from the centre of the Earth, then r^2/H is practically constant and independent of latitude.

If R is the Earth's local radius then:

$$\rho = \rho_0 \exp\left\{-\frac{r^2}{H}\left(\frac{1}{R} - \frac{1}{r}\right)\right\} \tag{1}$$

If e is the eccentricity of a satellite orbit, r_p is the radius at perigee, θ the anomaly, i the inclination, φ the angle from apex to perigee and ε the Earth's ellipticity, then:

$$r = \frac{r_p\,(1+e)}{1 + e\cos\theta} \tag{2}$$

$$R_p = R_{\text{max.}}\,(1 - \varepsilon\sin^2 i\cos^2\varphi) \tag{3}$$

$$R - R_p = R\varepsilon\sin^2 i\sin\theta\sin(2\varphi + \theta) \tag{4}$$

Let $\dfrac{R}{H_0}\,\varepsilon\sin^2 i = \beta$, then omitting terms which average out around the orbit:

$$\rho = \rho_p \exp\left\{-\frac{e}{1+e}\cdot\frac{r_p}{H_p}\,(1-\cos\theta)\right\} \times \left\{1 + \left(\beta\cos 2\varphi + \frac{\beta^2}{2}\sin^2 2\varphi\right)\sin^2\theta + \left(\frac{\beta^2}{2}\cos 4\varphi + \frac{\beta^3}{2}\sin^2 2\varphi\cos 2\varphi\right)\sin^4\theta + \ldots\right\} \tag{5}$$

If the eccentricity is not too small, practically all the retardation occurs near perigee, $\sin^4\theta$ is negligible and $\sin^2\theta = 2\,(1-\cos\theta)$, so that:

$$\rho = \rho_p \exp\left\{\left(2\beta\cos 2\varphi + \beta^2\sin^2 2\varphi - \frac{e}{1+e}\cdot\frac{r_p}{H_p}\right)\times(1-\cos\theta)\right\} = \rho_p\exp\{-\psi\,(1-\cos\theta)\} \tag{6}$$

Let $\psi = \dfrac{e}{1+e}\cdot\dfrac{r_p}{h}$, where h is the adjusted scale height.

If Ω is the satellite's angular momentum, C its resistance coefficient, m its mass per unit frontal area and S its distance of travel, then for a non-rotating Earth:

$$\frac{d(\log\Omega)}{dS} = -\frac{C\rho}{2m} \tag{7}$$

The Earth's rotation reduces the airspeed by an almost constant fraction which can be allowed for by a change in ρ_0.

Also

$$\frac{de}{d(\log\Omega)} = 2\,(\cos\theta + e) \tag{8}$$

$$\frac{dr_p}{d(\log\Omega)} = \frac{2r_p}{1+e}\,(1-\cos\theta) \tag{9}$$

$$\frac{dS}{d\theta} = \frac{r_p\,(1+e)}{(1+e\cos\theta)^2}\sqrt{(1 + 2e\cos\theta + e^2)}$$

$$= r_p\,(1+e)\left\{1 - e\cos\theta + \frac{e^2}{2}(1+\cos^2\theta) - \frac{e^3}{2}(3\cos\theta - \cos^3\theta) + \ldots\right\}$$

$$= r_p\,(1+e)\times\left\{1 - e^3 - (e-e^2)\cos\theta + \frac{\delta^2e^2}{2} + \frac{3\delta^2e^3}{2} - \frac{\delta^3e^3}{2}\right\} \tag{10}$$

$$\delta = 1 - \cos\theta$$

From (5) it is clear that the mean value of δe in the significant part of the orbit is of the order of $(1+e)\,h/r_p$, which is probably less than 0·01, so that δ^2e^2 will be negligible.

If then e^4 is negligible:

$$\frac{dS}{d\theta} = r_p\,(1+e)\{1 - e^3 - (e-e^2)\cos\theta\} \tag{11}$$

Using (6), (7), (11) and (8) or (9), exact solutions are obtainable for mean values around the orbit:

$$\frac{de}{d\theta} = -\frac{C\rho_p r_p\,(1+e)\,(1-e^2)}{m}\times\left\{\left(1+\frac{h}{r_p}\right)I_1(\psi) + e^2I_0(\psi)\right\}\exp(-\psi) \tag{12}$$

$$\frac{dr_p}{d\theta} = -\frac{C\rho_p r_p^2\,(1+e)\,(1-e^2)}{m}\times\left[I_0(\psi) - \left\{1 + \frac{h}{(1+e)\,r_p}\right\}I_1(\psi)\right]\exp(-\psi) \tag{13}$$

If $\psi > 2$ then, with an error of less than 1·5 per cent if $2 < \psi < 4$ and of 0·5 per cent if $\psi > 4$, we have:

$$\frac{dr_p}{d(\log e)} = \frac{h}{2(1+e)}\left(1 + \frac{2}{3}\cdot\frac{h}{r_p}\right)\times\left(1 + \frac{3}{4\psi} + \frac{3}{4\psi^2} + \frac{3}{2\psi^3}\right) \tag{14}$$

Since h is not constant this must be integrated numerically; however, integration is made easier by the fact that $d(e^2)/d\theta$ varies very little during the life of an artificial satellite.

If $\psi < 2$, the approximate formula (14) becomes very inaccurate and $\sin^2\theta$ can no longer be equated to $2(1 - \cos\theta)$, so that (5) must be used in its full form. The eccentricity, e, however, is so small that it can be omitted from the remainder of the formulæ.

Solutions are easily obtainable in terms of the Bessel functions I_0 and I_1, but they are rather long and only apply to the last few days of a satellite's life.

If the mean temperature between R and r_p falls from equator to poles the ellipticity of the surfaces of constant density will be increased. This can be allowed for by a change in ε.

For a mixture of gases of different molecular weights it is necessary to sum the values of (12) and (13) for the components. Values of H obtained from satellites with different perigee radii may give some information about the change of composition with height.

Thermo-electric Observations on Grey Selenium

The thermo-electric power of grey selenium has been accorded considerable attention in recent years, and Henisch and Francois[1], among others, have carried out accurate measurements and discussed their results in terms of a simple model. We wish to report some thermo-electric results, obtained in the course of an investigation of the photo-catalytic properties of this modification of selenium, which are at variance both with common experience and with these workers' model.

It seems to be experimentally well established that selenium is almost unique among semiconductors in having a thermo-electric power with a positive temperature coefficient: this can be explained[1] by assuming that the activation energy of the semiconductor is so small that most of the impurity centres are normally ionized. By submitting selenium to repeated vacuum distillations followed by recrystallization, we have prepared spectrographically pure samples, from which a few substantially monocrystalline ingots were grown by the Bridgman technique. Most of the ingots, however, consisted of bundles of large grains all having their c-axis parallel to the growth direction (oriented polycrystals). Thermo-electric power measurements on ingots of both types, extending over many months, yielded results of marked qualitative difference. As shown in Fig. 1, the oriented polycrystal specimen has a thermo-electric power which increases with temperature, and further exhibits hysteresis and secular changes, since the scatter of the points is much worse than the measurement error (of the order of 1 per cent at all but the lowest temperatures). Both these features have been reported to be of common occurrence with monocrystalline as well as with polycrystalline samples[2]. We found, however, that monocrystals showed a thermo-electric power quite independent of temperature, and insensitive to thermal history. The scatter of results below −100° C. is due to the rapidly increasing resistance of the specimen (upwards of 10^{10} ohms), which impaired the precision of the measurement, carried out by means of an integrating potentiometric circuit already described[3].

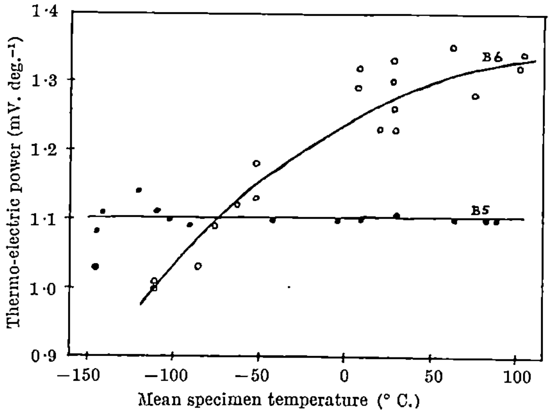

Fig. 1. Thermo-electric power of grey selenium crystals. *B5*, single crystal; *B6*, oriented polycrystal

New Supersonic Phenomena

Polarized light has been used for determining the propagation of stress waves in solids for some time. We have employed it to study the propagation of stress waves in glass and plastics and have found what we believe to be evidence of new supersonic phenomena. The experimental arrangement follows classical lines, using 'Polaroids' and quarter-wave plates that give circularly polarized light through the transparent sample. For illumination, we used a 1530 *PI* discharge tube (General Radio) with an effective flash duration of 2 μsec. The transparent sample was loaded by exploding small amounts of lead azide with an electric 'bridge'. The timing between the flash and the explosion was achieved by a suitable electric timer which allowed a variation of the delay from zero to 30 μsec. It is well known that shock loading causes a compressional and a shear wave to be propagated in the material, both of which essentially follow the so-called Huygens construction.

However, our 'single shot' tests showed that, far in advance of the compressional wave, which has a speed of propagation of 5,500 m./sec. in glass, dark lines occurred at the far corners of the rectangular specimen at about 45°. These dark lines appear as much as five times as early as the compressional wave could have reached the point. We also investigated 'meeting shots' where two explosive charges at the centres of the short ends of a sample of glass,

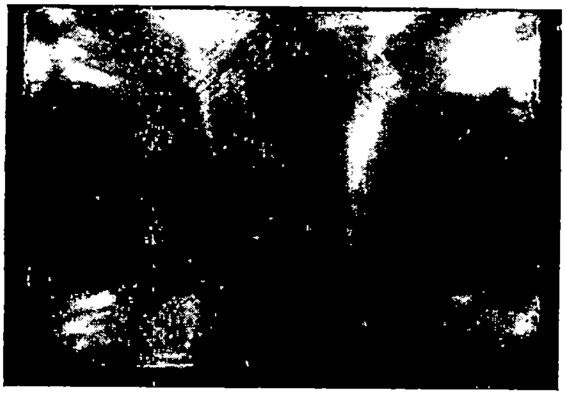

Fig. 1

4 in. × 6 in., were exploded in series. When the delay was such that the compressional waves were propagated about 1 in. into the sample, a very sharp pattern of parallel lines was observed in the centre of the sample much in advance of the compressional wave. Similarly, parallel line patterns were observed near the sides of the sample, as is seen in Fig. 1. The conditions of operation were: 10·6 μsec. after explosion on a glass plate 80/1,000 in. or 2 mm. thick using 13 mgm. lead azide. Similar photographs have been made in colour and have shown that the blue interference patterns have a completely different colour from the reddish-yellow one of the explosion.

Both the 'single shots' and the 'meeting shots' give evidence of phenomena occurring up to about five times faster than the compressional speed of sound, or up to a speed of about 30,000 m./sec. in glass. Similar investigations made on plastics, for example, methylmethacrylate ('Lucite') and *CR*39 resin, showed basically the same phenomena but much less distinctly, apparently damped out. We have investigated the possibilities of experimental errors causing these theoretically unexpected wave phenomena in solids but have not been able to find any. The phenomena photographed are faint as compared with the intensity of the compressional wave; however, they seem to be standing waves, whereas the compressional waves move with the velocity of sound. Therefore, the use of a 2 μsec. flash which gives a blurred picture of the compressional wave results in sharply defined traces of the supersonic pattern. The charge used seems to be an optimum for the detection of the phenomena in glass. The patterns depend on the thickness of the sample: they are sharper with thin plates, their spacing increasing linearly with the thickness.

Experiments using an electrical delay line between the (parallel) charges show a shift of the meeting pattern equivalent to the speed of the compressional wave.

The patterns described are completely different from the 'regular' ones obtained by the Huygens construction and are essentially rectilinear and parallel to the sides of the samples. The phenomena could be caused by a very fast wave propagated on the surfaces of the sample, with the two compressional waves generated interfering to produce the pattern by exciting thickness vibrations of the plate. We have found no evidence that these phenomena move at all. The estimated speeds given above are deduced from observing the phenomena ahead of the compressional wave and are not really measurements of velocities; rather they represent a lower limit for the velocity of propagation of these supersonic phenomena.

I have also observed the formation of cracks in glass progressing with the speed of the compressional wave, and even ahead of it, as compared to the crack propagation speed of $\frac{1}{2}\sqrt{E/\rho}$ generally accepted. The cracks are irregular, occurring apparently at flaws in the sample, again departing from the usual radial cracks in impact loading. These observations tend to confirm the reality of the new phenomenon.

Further details of this work will be reported elsewhere. It is being supported by the Office of Ordnance Research, Duke University, Durham, North Carolina.

Crystal Structure of β-Wollastonite

β-WOLLASTONITE ($CaSiO_3$) comprises both triclinic wollastonite and monoclinic parawollastonite[1]. These forms are not easily distinguishable except by single-crystal X-ray work, since they differ only in the reflexions with k odd, and these are always weak. A new type of infinite-chain silicate structure has recently been proposed[2] for β-wollastonite from X-ray crystallographic work on projections. The three-dimensional work on parawollastonite from Crestmore, California, which is reported here confirms this type-structure.

The cell parameters of parawollastonite are: $a = 15{\cdot}417 \pm 0{\cdot}004$ A., $b = 7{\cdot}321 \pm 0{\cdot}002$ A., $c = 7{\cdot}066 \pm 0{\cdot}002$ A., $\beta = 95° \; 24' \pm 3'$, $G = 2{\cdot}922$, $Z = 11{\cdot}95$ formula units. The systematic absences are: in hkl, $(2h + k) = (4n + 2)$, which can only apply to terms with k even, and in $0k0$, $k = (2n + 1)$. The space group is $P2_1$, with $6CaSiO_3$ in the asymmetric unit of half the cell. The absence in hkl implies further symmetry, in that there must be equivalent, non-lattice, points at 0,0,0; $\frac{1}{2}, \frac{1}{4}, 0$. The positions of equivalent atoms are thus $(0, 0, 0; \frac{1}{2}, \frac{1}{4}, 0) + x, y, z; \; \bar{x}, \frac{1}{2} + y, \bar{z}$; so that only three units of $CaSiO_3$ are crystallographically independent. No centre of symmetry can be assumed; physical tests for this were inconclusive.

The hkl reflexions with k even are relatively strong, which implies a concentration of atoms about the planes $(2n + 1)b/8$. If these planes have limited mirror symmetry[3], the space group becomes the centrosymmetric $P2_1/a$. After preliminary work on a chain structure assuming this space group, on which refinement was not satisfactory, atoms were shifted slightly to give a non-centrosymmetrical structure on which refinement is progressing well. A three-dimensional Fourier synthesis with more than 1,300 observed reflexions has been computed, on which there were no unidentifiable peaks. The [001] projection of the resulting structure is shown in Fig. 1. The atomic maxima on this Fourier synthesis were close to the atomic positions used in the calculation of phases; the directions of the shifts indicate no tendency to return to a centrosymmetric structure.

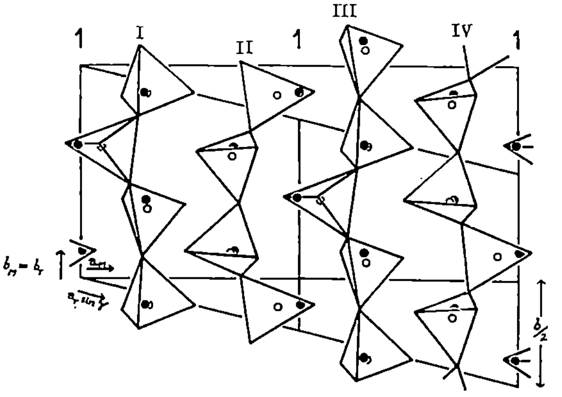

Fig. 1. Parawollastonite structure projected down [001]. ●, calcium atoms; ○, silicon atoms; oxygen atoms at apices of tetrahedra. Axes of monoclinic cell have subscript M, of outlined triclinic cells subscript T

The parawollastonite structure has infinite chains of silicon tetrahedra parallel to the b-axis, as is suspected from its fibrous habit. The repeating unit of three tetrahedra in the chain consists of a pair of tetrahedra joined apex to apex, as in the Si_2O_7 group[4], alternating with a single tetrahedron with one edge parallel to the chain direction. The calcium co-ordination is irregular, though all calcium atoms are co-planar with four near oxygen O^{1-} atoms and have distorted octahedral co-ordination. The atom almost on the screw diad axis has seven oxygen atoms within 2·6 A. of it, one of which is already bonded to two silicon atoms. The other two calcium atoms have almost identical environments. At one apex of the octahedron is an oxygen O^{0-} already bonded to two silicon atoms; at the opposite apex is an oxygen O^{1-} bonded only to one silicon atom. In these octahedra there are two oxygen O^{1-} atoms bonded only to two calcium atoms, instead of three, and to one silicon atom. Pauling's rules are thus satisfied by the addition of charges from the six oxygens around Ca^{2+} of $(3 \times \frac{1}{3} + 2 \times \frac{1}{2} + 1 \times 0) = 2$.

The close relationship between the β-wollastonites is shown in Fig. 1, where two wollastonite cells have been outlined on the one parawollastonite cell; the c-axes are equal. Chains III and IV are not in the same relative orientation as chains I and II in parawollastonite: the symmetry of wollastonite requires that they should be, which can be achieved by shifting chain IV by $b/2$. Since the difference between parawollastonite and wollastonite depends only on a simple packing modification, the close intergrowth of the two is easily explicable.

Tetrahedral Co-ordination in Ni(II)

Two forms of Ni(II) compounds have been recognized for a long time, the green paramagnetic forms and the (yellow) diamagnetic forms. The nature of these has been described in terms of electronic structure by Pauling[1], as a paramagnetic 6-co-ordinate form with two unpaired electrons and a square planar form with hydridized orbitals leading to diamagnetism through electron pairing. The magnetic criterion has been completely satisfactory in differentiating these two. There is another 4-co-ordinate configuration theoretically possible, namely, the tetrahedral, which also would have two unpaired electrons. No obvious criterion presents itself for differentiation of this from the octahedral 6-co-ordinate condition.

There are occasional Ni(II) compounds which are blue, and some of these have been studied magnetically by Lifschitz, Bos and Dijkema[2]. The conclusion of these workers was that these compounds were tetrahedral. More recent reports on this identification of possible tetrahedral Ni(II) compounds have been from workers interested in geometrical properties of organic chelating agents, and from those interested in the ligand field type of explanation of transition element spectra and binding. The detailed calculations carried through on this latter basis have apparently not given any clear assignment by spectral relations or other obvious criterion (for example, Maki[3]).

Low[4] has investigated the paramagnetic resonance and optical spectra of Ni(II) in magnesium oxide (MgO) crystals, with a rigid octahedral symmetry imposed by the crystal structure. From his work, the relatively strong sharp peak of the Ni(II) absorption spectrum which is found normally around 400 mμ is due to a transition $^3F(\Gamma_2)$–$^3P(\Gamma_4)$. The highest of the three ^3F levels into which the free-ion ^3F groundstate is split is Γ_4. In the inversion of levels in changing to tetrahedral field[4, 5], the Γ_2 level as groundstate would be replaced by a Γ_4 level. As this $^3F(\Gamma_4)$ should no longer give a relatively strong transition to the $^3P(\Gamma_4)$ level[6], as did the Γ_2 groundstate, the corresponding 400-mμ absorption peak should vanish.

In studies of the absorption spectra of inorganic salts in non-aqueous media, in which this Laboratory has had an interest, experiments have been performed in tributyl phosphate and in acetone media which bear on this question. In acetone, for example, very dilute solutions of nickelous perchlorate (about 2×10^{-4} M—concentrations are chosen to minimize precipitation of nickelous chloride after addition of chloride) are green, and show the characteristic peak at about 410 mμ. Addition of up to two equivalents of lithium chloride intensifies the peak (as it does those at longer wave-lengths), and shifts it to about 423 mμ. Further additions of chloride, however, while still intensifying the peaks at longer wave-lengths, cause the 425-mμ peak to diminish in intensity, and by a composition with four chlorides per nickel, essentially to vanish. In the intermediate stages there is a suggestion that the peak may be splitting into two. The colour of the solutions is a deep blue, reminiscent of the blue cobalt colour, and the spectra at high chloride ratios (for example, 9 : 1 also somewhat resemble those of $CoCl_4^{2-}$. After some hours or a day, even these dilute solutions tend to deposit nickelous chloride. Similar observations were made in the tributyl phosphate solutions.

If a solvent such as *iso*propyl alcohol is used instead of the above, one gets only intensification of peaks even for anion–nickel ratios greater than two. This holds for both chloride and thiocyanate. It is interesting that study of continuous variations of these solutions shows a maximum apparent complexing of four anions per nickel[7]. This apparent limit might be due to problems of replacing further solvent groups, rather than an indicator of pure 4-co-ordination, as the alcohol is a stronger electron donor than acetone, and tends to maintain the higher co-ordination number of cations[8] (with iodide, co-ordination to six groups per nickel can be seen). It might be added that Ni(II) in fused nitrate salt melts is green, and that a blue colour develops on addition of chloride, with a spectrum similar to that of our blue acetone solutions (D. Gruen, private communication). Small amounts of nickel incorporated into solid Cs_2ZnCl_4 (tetrahedral $ZnCl_4^{2-}$) also show the same blue spectrum.

It is therefore suggested that the blue compounds studied by Lifschitz, Bos and Dijkema[2] were in fact tetrahedral, as is also the chloride (in excess chloride) in acetone and tributyl phosphate. The blue colour arises mainly by disappearance of the 410-mμ peak, as would be predicted from Low's[4] analysis of the levels for the Ni(II) ion in the octahedral crystalline field. One may venture to state the following generalization: paramagnetic nickelous compounds which are the normal green colour, or the spectra of which show the equivalent of the 410-mμ absorption peak of the green form, are to be presumed to be 6-co-ordinate, or at least to possess the electronic structure characteristic of the 6-co-ordinate state. Paramagnetic compounds of Ni(II) which fail to show this absorption peak (and which may be blue, if the colour is not masked by the ligand) are presumably tetrahedral, or have the equivalent electronic structure. Diamagnetic compounds have, of course, the square planar form.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Production of Methane from Carbon

The recent work of Blackwood and McGrory[1] has shown that methane is formed when carbon, in the form of coconut char, is allowed to react with steam under pressure. The rate of formation of methane is a linear function of the steam pressure and appeared to be independent of the partial pressure of hydrogen when the latter is small. A similar study[2] of the reaction of hydrogen and carbon under pressure at temperatures of 650–950° C. has shown that the rate of formation of methane is a linear function of the hydrogen pressure and that the addition of small amounts of steam to the atmosphere of hydrogen has no apparent effect on the rate of formation of methane. It is suggested that the mechanism of methane formation is the same. The rate of formation of methane, for the same carbon, prepared at 950° C., with 30 atm. of steam at 870° C., is 16×10^{-5} gm.mol./min./gm. carbon, and with hydrogen under the same conditions is 10×10^{-5} gm.mol./min./gm. carbon. The rate varies with the temperature of preparation of the carbon and lower-temperature carbons are more reactive, reaching a maximum reactivity to hydrogen when prepared at about 750° C.

Similar results were obtained by Goring *et al.*[3] in the gasification of 'Disco' char with a steam–hydrogen mixture at 870° C., their results showing that there is no significant change in the rate of formation of methane at a given temperature and pressure when the reactant gases are mixtures of steam and hydrogen in the ratios 50/50, 75/25 and 90/10. Their gasification-rate at 870° C. and 30 atm. pressure was approximately 33×10^{-5} gm.mol./min./gm. carbon, and later experiments in the same apparatus with similar char[4], using hydrogen only as the reactant gas, gave a rate of 40×10^{-5} gm.mol./min./gm. carbon. Wood charcoal, prepared at 870° C. from *Eucalyptus marginata*, when made to react with hydrogen under the same conditions of temperature and pressure, gave[2] a rate of formation of methane of approximately 45×10^{-5} gm. mol./min./gm. carbon.

It has been suggested[1] that the carbon–steam reaction is controlled by oxygen groups attached to the carbon and that the methane produced is formed by reaction of steam with adsorbed hydrogen, liberating methane and carbon monoxide. The formation of methane by reaction of hydrogen with carbon is believed to be controlled by oxygen groups, such as chromene or benzpyran, in the carbon structure[2], and it now appears that these may be effective in controlling methane production in both the carbon–steam and carbon–hydrogen reactions.

The formation of methane during the carbon–steam reaction is important technically since it results in a reduced heat requirement for the gasification of carbon with steam due to the exothermic nature of the reaction producing methane.

Paper as a Carrier of Chromium Sesquioxide

Chromium sesquioxide (Cr_2O_3) is widely used for estimating feed digestibility[1] or fæces output[2] by ruminants, but such estimates may be subject to considerable errors because the concentration of this marker in fæces normally shows considerable diurnal variations even after prolonged regular administration. These variations are particularly obtrusive with grazing animals where the chromium sesquioxide, in

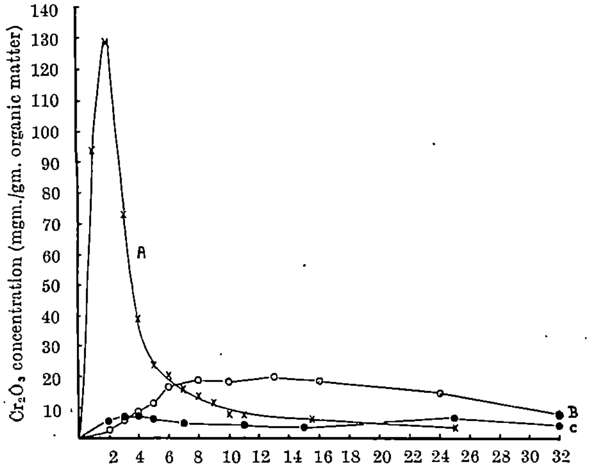

Fig. 1. Concentrations of chromium sesquioxide expressed as mgm./gm. organic matter in digesta drawn from the duodenum of a sheep following the administration of single doses of chromium sesquioxide: *A*, as the powder in a gelatin capsule; *B*, in paper; *C*, in plaster of Paris

this case used for estimating the output of fæces, is usually administered in concentrated powder form in gelatin capsules once or twice daily, and they probably arise primarily from an imperfect mixing of the oxide with digesta in the reticulo-rumen[3,4]. This view is supported by unpublished observations (by J. F. D. Greenhalgh) on the concentrations of chromium sesquioxide in the organic matter of digesta obtained from the duodenum of a sheep permanently cannulated at this point. As the variations in concentration during a period of regular dosing showed the same pattern and were greater than those found in the fæces, it was decided to study in a comparably cannulated sheep the passage of single doses of oxide powder, each given in a gelatin capsule and in amount large enough to give measurable concentrations over a considerable period of time. Samples of digesta were drawn from the duodenum at intervals beginning 1 hr. after dosing. Results from a typical run where 8 gm. were given are shown in Fig. 1 (line *A*) and indicate that a large part of the dose had passed from the stomachs within 4 hr. of administration. The probable explanation is that the capsule container dissolved quickly in the anterior rumen or reticulum[3] and that local concentrations of chromium sesquioxide in these regions[4] were rapidly transferred through the reticulo-omasal orifice.

Properly to fulfil its function as a marker, chromium sesquioxide should be cleared from the reticulo-rumen at a rate as nearly as possible equivalent to that of the food dry matter, or any of its constituents under study. Since this condition does not appear to be met by dosing with capsules containing loose oxide, some method of obtaining a slower and more regular release of chromium sesquioxide into digesta appears desirable. An attempt to do this has been made by incorporating the oxide in paper. A small quantity of paper was made by beating chromium sesquioxide in a 3 per cent stock (that is, 97 per cent water) of fully bleached sulphite wood pulp to which was added aluminium sulphate (paper-makers' alum) at 1 per cent of the dry matter. With the method employed it was found possible to obtain a paper containing 20–30 per cent chromium sesquioxide in the dry matter. It was found at this stage that Edin[5] had already suggested the use of a material termed 'chrome-cellulose' for determining the digestibility of rations consisting wholly of roughage. This material, resembling blotting paper, was prepared from a mixture of chromium sesquioxide and paper pulp, but apparently aluminium sulphate was not added. The 'chrome-cellulose' was cut into small strips and mixed with the chopped fodder, but it does not appear to have been tested or used to any large extent. In our experiments, which were concerned primarily with the development of a technique for estimating the output of fæces by grazing animals, the required amount of dry sheet, containing approximately 8 gm. chromium sesquioxide, was cased in gelatin capsules for dosing. It was tested by the rapid method afforded by the examination of digesta passing through the duodenum and one set of results is shown by line *B* in Fig. 1. There was no sign of a rapid passage of chromium sesquioxide through the stomachs; instead concentrations of the oxide steadily increased for 8 hr. after dosing and then remained at approximately the same level for at least a further 8 hr. before slowly declining.

A 'slow-release capsule' devised by Pigden and Brisson[6], which is claimed to reduce variations in concentrations of chromium sesquioxide in fæces, has also been tested. This capsule consisted of equal parts of chromium sesquioxide and plaster of Paris and was cast in a gelatin capsule. Its administration gave the results shown by line *C* in Fig. 1. Again there was no sign of a rapid passage of the oxide, and concentrations remained at approximately the level reached 2 hr. after administration for at least a further 40 hr.

Both methods of administration, in paper or in plaster of Paris, appear to be superior to the administration of the oxide in powder form, but it is believed that chromium sesquioxide paper possesses very considerable advantages. It was found by microscopic examination, using polarized light, that the effect of the aluminium sulphate was to attach the individual oxide particles to the cellulose fibres of the paper so that relatively few free particles were to be found after agitation in water. In addition a large proportion of the oxide appeared still to be attached to partially digested cellulose fibres and closely associated with organic debris in the duodenum. In this respect chromium sesquioxide is equivalent to a naturally occurring marker such as lignin, but possibly without the chief disadvantage of the latter, which appears to be the slower digestion and rate of passage through the alimentary tract of those fractions of the feed containing lignin in greatest concentration[7]. On the other hand, neither the oxide from the ordinary capsule nor that derived from the plaster of Paris capsule showed any marked degree of association with organic matter.

It is considered that the general pattern of the passage of chromium sesquioxide derived from the digestion of the paper, illustrated in Fig. 1, might more nearly approach that of the products of digestion of the food than the passage of the oxide derived from the slow erosion of a mineral matrix although, as has been pointed out elsewhere[4], it is unlikely that any marker can exactly parallel the behaviour of 'dry matter' as such in the gut.

Work is in progress to determine the optimum composition of chromium sesquioxide paper and to discover the pattern of excretion in fæces.

We thank Dr. P. Hobson of the Rowett Research Institute for carrying out the microscopic examinations. One of us (J. F. D. G.) is in receipt of a Drummond Junior Fellowship for Research in Nutrition.

The Problem of Negative Anharmonicity and the Nature of the Hydrogen Bond in Potassium Hydrogen Fluoride

There are many short hydrogen bonds which have been claimed to be symmetrical, but it is only in the case of potassium hydrogen fluoride that all the experimental evidence indicates that the proton is central. Yet in this substance there are still some problems to be cleared up, one of them being the hypothetical divergence of the protonic vibrational levels. Besides, as will be shown, the experimental results, which were thought to be explainable only in terms of a symmetrical model, may be explained in another way.

Cote and Thompson[1] explained the whole spectrum of the hydrogen fluoride ion between 1,225 cm.$^{-1}$ and 6,196 cm.$^{-1}$ in terms of the selection rules which would be expected for a linear symmetrical structure ($D_{\infty h}$). They found an apparently large negative anharmonic coefficient for the overtone and combination bands of the asymmetric stretching vibration frequency. Following a suggestion of Pitzer and Westrum[2], they explained this divergence of the protonic vibrational levels by assuming a fourth-power potential field: $V(x) \propto x^4$.

However, it can be generally shown that for fields where the potential energy varies for small displacements as the nth power of the displacement (n being a positive number), the isotopic ratio becomes $\nu_H/\nu_D = (m_D/m_H)^{n/n+2}$. In the special case of harmonic forces, n is 2, and $\nu_H/\nu_D = \sqrt{2}$. In the case of a fourth-power potential field[3], the isotopic ratio ν_H/ν_D should be greater than $\sqrt{2}$ (say, 1·59), whereas it actually is 1,450/1,046 = 1·387.

In view of this controversy the question arises whether the divergence of the vibrational levels is due to a false assignment of combinations and overtones. On the other hand, if this divergence of vibrational levels is real, it could be explained by a quite different mechanism, namely, by assuming that hydrogen fluoride represents an intermediate case between a symmetrical oscillator and an oscillator having a double minimum in the potential function. This implies that the barrier is shallow, and that its height is much lower than the lowest energy-level. The vibrational energy-levels would be split into doublets; the splitting would increase with increasing vibrational quantum number until it would be equal to half the separation of successive unperturbed levels. The divergence of the vibrational levels would be more pronounced the higher the potential barrier.

In view of this possibility, we decided to reanalyse all arguments leading to the assumption of symmetrical hydrogen bonding in hydrogen fluoride.

Proton nuclear magnetic resonance measurements[4] and neutron diffraction[5] showed that the equilibrium position of the proton lay within ± 0·06 A. and ± 0·1 A., respectively, of the centre of the ion axis. This does not exclude the possibility of a small and shallow barrier with $2l$ less than 0·12 A.

Pitzer and Westrum proposed a symmetrical structure on the grounds of the absence of a heat capacity peak in the low-temperature region. But as they point out themselves[6], thermodynamic data could not eliminate the possibility of a potential hill so small that the zero energy-level splitting would be greater than 70 cm.$^{-1}$. The possibility of such a splitting was abandoned in view of spectroscopic arguments, which will be discussed later.

Another argument which seemed to favour the symmetrical structure arose from dielectric constant measurements[7]. The dielectric constant of potassium hydrogen fluoride is low (4·1), and is, moreover, nearly independent of temperature. It was suggested that in the case of a double minimum there would be an orientable dipole and a high temperature-dependent dielectric constant would result. However, it can be shown by quantum-mechanical methods that this argument holds only in the case of a large barrier, and thus does not apply to the present case.

Spectroscopic arguments remain. The assignment of the 1,450 cm.$^{-1}$ band as ν_3 and the 1,222 cm.$^{-1}$ as ν_2 is assured[8] and so no doubling of ν_3 is observed. This fact was supposed to eliminate definitely the possibility of a double minimum potential field, but can be explained as follows: if the barrier is very small, then this may be considered as a case intermediate between a double minimum and a symmetrical single minimum oscillator. Calculations show that the zero energy-level splitting might be as large as 1,450 cm.$^{-1}$. The selection rules for a resonance between two $C_{\infty v}$ structures go over into those for a $D_{\infty h}$ structure. The ν_3 band at 1,450 cm.$^{-1}$ can thus be identified with a $v_{0+} \leftrightarrow v_{0-}$ transition. The $3\nu_3$ band at 5,099 cm.$^{-1}$ may be identified with the $v_{0+} \leftrightarrow v_{1-}$ transition, and as the intensity of the $v_{0-} \leftrightarrow v_{1+}$ transition ($2\nu_3 \leftrightarrow 3\nu_3$) is negligibly small owing to the Boltzmann factor, no second double minimum band can be found. The transition $v_{0+} \leftrightarrow v_{1+}$ ($2\nu_3$) would be forbidden by the selection rules.

Hence, except for the explanation of the hypothetical divergence of the vibrational levels, it is a matter of convenience whether we say that the hydrogen bond in potassium hydrogen fluoride is a symmetrical one or that it represents a limiting case of the double minimum type.

I wish to thank Prof. D. Hadži for stimulating and helpful discussions and Prof. A. Peterlin for reading the manuscript critically.

Synthesis and Structure of 2,6-Dihalo-Benzenone-Indophenylacetate and Benzenone-Indo-3′,5′-Dihalo-Phenylacetate

Hitherto only one compound has been isolated after the esterification of dihalo-benzenone-indophenol with acetic anhydride; this compound was assumed to be 2,6-dihalo-benzenone-indophenylacetate[1]:

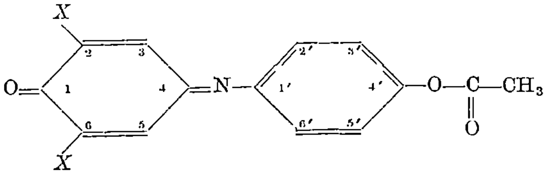

Fig. 1

It is, however, possible to obtain two different acetates—an orange and a red one—from dihalo-benzenone-indophenol, depending on the conditions during the preparation. The two compounds have the same molecular weight and composition, but different colours, melting points, infra-red and ultra-violet spectra and rates of hydrolysis with enzymes.

Red dichloro compound. The red compound was synthesized by a method analogous with Heller's for the preparation of benzenone-indophenylacetate[2]. 5·8 gm. (0·02 mole) of the sodium salt of 2,6-dichlorobenzenone-indophenol in 25 ml. dry ether were heated for 30 min. at 35° C. with 12 gm. acetic anhydride. After cooling, the reaction mixture was put into a beaker containing 500 gm. crushed ice and well stirred for several hours. The ester crystallized; it was filtered off, dried and recrystallized from ether. It formed red crystals, m.p. 99·5°–100·5° C., yield 3·7 gm. (60 per cent), analysis calculated (per cent): C 54·2, H 2·9, N 4·5, Cl 22·9; found: C 54·1, H 2·9, N 4·4, Cl 22·9.

Orange dichloro compound. A modification of a method of Kramer, D. N. (private communication), was used for the preparation of the orange compound. 5·8 gm. (0·02 mole) of the sodium salt of 2,6-dichlorobenzenone-indophenol in 25 ml. dry ether were heated for 15 min. at 35° C. with 2·04 gm. (0·02 mole) acetic anhydride. After cooling, 1 ml. dry pyridine was added. Heating was continued for 15 min. After cooling, the reaction mixture was put in a beaker containing 500 gm. crushed ice and well stirred for several hours. The ester crystallized; it was filtered off, dried and recrystallized from acetone-ether. It formed orange crystals, m.p. 68–69° C., yield 4·3 gm. (70 per cent), analysis calculated (per cent): C 54·2, H 2·9, N 4·5, Cl 22·9; found: C 54·2, H 2·9, N 4·4, Cl 22·9. The corresponding dibromo-compounds were synthesized in the same

2,6-dihalo-benzenone-indophenylacetate

benzenone-indo-3′,5′-dihalophenylacetate

Fig. 4

way. Paper chromatography showed that each compound could be obtained free from its isomer.

When, however, methods 1 and 2 are applied in the preparation of 2,6 dihalo-benzenone-indo - 3′ 5′-dihalophenylacetate, identical products are obtained. The same holds for the preparation of benzenone-indophenylacetate.

We assume that the formation of the two different compounds is due to mesomerism of the indophenol ion or to tautomerism of the indophenol molecule :

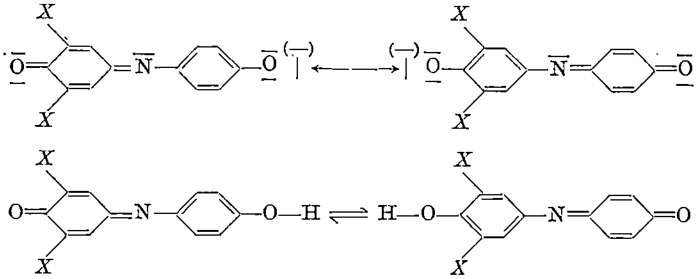

Fig. 2

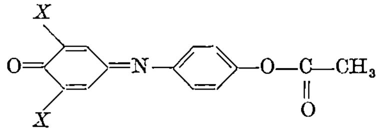
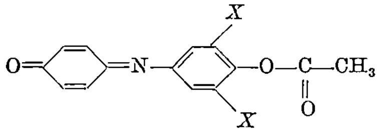
In that case there are two possibilities for the formation of dihalo esters :



2,6-dihalo-benzenone-indophenylacetate

and



benzenone-indo-3′5′-dihalophenylacetate

Fig. 3

By studying the infra-red spectra it is possible to determine which of the two structures belongs to the red ester and which to the orange one. Since no groups are characteristic for either of the two structures only frequency shifts due to interactions with surrounding atoms can be taken as a starting point. For this purpose the strong $C=O$ and $C-O-C$ bands were chosen. Generally $C=O$ stretching bands are shifted to higher frequencies when halogen atoms are substituted at a carbon atom next to the $C=O$ group[3]. The influence of halogen atoms in model compounds was studied. The results are shown in Table 1.

From Table 1 the position of the bands can be predicted for the following compounds.

The results obtained with the infra-red spectra of the compounds under consideration are shown in Table 3.

Table 3

Compound	Observed wave number (cm.$^{-1}$)		
	Quinonic $C=O$	Acetoxy $C=O$	$C-O-C$
	1648	1758	1190
Red dichloro compound Red dibromo compound	1665 1662	1753 1755	1189 1195
Orange dichloro compound Orange dibromo compound	1648 1646	1768 1778	1182 1179
Tetrachloro compound Tetrabromo compound	1673 1668	1782 1770	1173 1166

The most characteristic shift is shown by the quinone $C=O$ band. The other shifts can be considered as giving additional evidence for the assignment. Comparison of experimental results with the predicted values leads to the conclusion that the structure of the red and the orange compound is as shown in Fig. 4.

Note added in proof. While this letter was in the press, Dr. D. N. Kramers has informed us that he has obtained results similar to our own.

Transport of Vitamin A Ester in Rat Serum

It has been established in this laboratory that vitamin A alcohol is associated with the α_1-globulin of rat serum, but not with the low- or high-density lipoproteins and probably also not with the α_1-glycoprotein[1]. In continuation, the absorption of vitamin A alcohol and its transport to the liver as the ester have been studied.

Normal stock rats of the Wistar strain (vitamin A reserves of the liver ± 3,000 I.U./gm.) were put on a vitamin A deficient diet for 48 hr. and were then fed 500 I.U. of vitamin A-2-^{14}C (1·07 mc./mmole) in 0·2 ml. purified peanut oil by stomach tube. Under these conditions no vitamin A ester could be detected in the blood before feeding, but the vitamin A absorbed after administration of the dose should appear in the blood in the esterified form. After administration of the labelled vitamin A, blood samples were collected from the tail at intervals, combusted and counted as barium carbonate in a proportional counter converter (Nuclear Measurements Corporation, type *PCC*-10). The

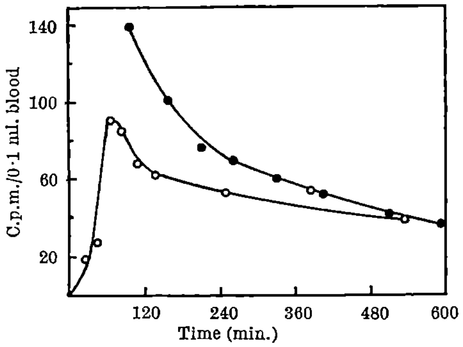

Fig. 1. Appearance of radioactivity in the blood of rats after dose of vitamin A-2-^{14}C (1·07 mc./mmole). ●—●, Rat 1; ○—○, rat 2

radioactivity in the blood reached a maximum after 1½–2 hr. (Fig. 1).

A group of ten stock rats was similarly treated and after 1½ hr. blood was drawn from the dorsal aorta, allowed to clot for 2 hr., and the serum collected and pooled. The lipoproteins were isolated by ultracentrifugal flotation fractionation at solution densities of 1·063 and 1·20 gm./ml. in the Model *E* analytical 'Spinco' ultracentrifuge[2] and directly combusted. The salt concentration of the sedimented proteins was lowered by dialysis and aliquots were afterwards combusted. For vitamin A alcohol and ester estimations, the serum samples were extracted, the alcohol and ester separated by chromatography on alumina[3] and determined by the Carr–Price colour reaction. Samples of the ester and alcohol fraction were also combusted. The carbon dioxide obtained from the combustions was assayed for radioactivity. The results of the analyses are summarized in Tables 1 and 2.

Tables 1 and 2 show that the value obtained by Carr–Price estimation of the vitamin A ester content of serum correlates well with the vitamin A levels, as calculated from radioactivity measurements on either the isolated lipoprotein or vitamin A ester fractions. It further appears that part of the normal serum vitamin A alcohol content of ± 100 I.U./100 ml. was replaced by labelled vitamin A, since the vitamin A alcohol fraction as well as the sedimented proteins, which transport vitamin A alcohol, contained radioactivity.

Table 1. ANALYSIS OF VITAMIN A ALCOHOL AND ESTER FRACTIONS AFTER EXTRACTION FROM SERUM

Description of analysis	I.U./100 ml. serum		
	Ester	Alcohol	Total*
Carr-Price colour reaction after chromatographic separation	127	98†	
Calculated from radioactivity measurements after chromatographic separation	149	27·7	176·7

Table 2. DISTRIBUTION OF VITAMIN A BETWEEN THE PROTEIN FRACTIONS OBTAINED BY ULTRACENTRIFUGAL FLOTATION FRACTIONATION

Description of analysis	I.U./100 ml. serum		
	Lipoprotein fraction	Sedimented proteins	Total*
Calculated from radioactivity measurements on fractions obtained at solution density 1·063 gm./ml.	132·7	38	170·7
Calculated from radioactivity measurements on fractions obtained at solution density 1·20 gm./ml.	130·1	34·6	164·7
Calculated from radioactivity measurements on whole serum			177

* Total refers to labelled ester and alcohol only.
† Consists of both labelled and unlabelled material.

In rat serum, vitamin A ester is therefore transported by the low density lipoproteins. A similar result was recently reported for human plasma[4]. It is interesting to note that the transport of vitamin A ester is similar for man and the rat, despite the species difference.

Mention should be made that the proteins, after extraction of vitamin A ester and alcohol, contained low residual radioactivity. This is probably due to a vitamin A transformation product, since it was found that, on feeding labelled vitamin A to vitamin A deficient rats, the excretion of radioactivity in the urine reached a maximum after 6 hr. and then rapidly decreased (Garbers, C. F., unpublished results).

This communication is published by permission of the South African Council for Scientific and Industrial Research. I thank Prof. J. Gillman, who suggested the vitamin A transportation problem, and Dr. D. A. Sutton for many helpful discussions, Mr. P. C. van Berge for assistance in the ultracentrifugal experiments and Dr. M. Peisach for radioactivity determinations.

Effect of Diet on Imidazole Compounds and Creatine in Chinook Salmon

HALVER[1,2] has recently devised highly purified diets for the Chinook salmon (*Oncorhynchus tshawytscha*), which have been used to determine the amino-acid and vitamin requirements for this species[2,3]. Since the muscle of the salmon contains both free histidine and anserine[4], it was of interest to determine the content of these imidazole compounds in the muscles of histidine-deficient fish. Samples of these and also of control and methionine-deficient salmon were made available to us through the courtesy of John E. Halver, U.S. Fish and Wildlife Service, Cook, Washington. The weight of the histidine and methionine-deficient fish over a ten-week feeding period was relatively constant at 1·8 gm., whereas the control fish increased in weight from 1·8 to 3·3 gm. The skeletal muscles of four fish in each group were combined and were analysed for histidine, 1-methylhistidine, carnosine and anserine by the ion-exchange method of Davey[4,5], and also for creatine and creatinine by the method of Van Pilsum *et al.*[6]. Non-protein nitrogen was determined by micro-kjeldahl. Results are shown in Table 1.

Although histidine is an essential amino-acid for these fish[3], it is present in the muscle in relatively

Table 1. EFFECT OF DIET ON SOME SKELETAL MUSCLE CONSTITUENTS OF CHINOOK SALMON

Sample diet	Histidine	1-Methyl-histidine	Carnosine	Anserine	Non-protein nitrogen (mgm./gm.)	Creatine (mgm./gm.)	Creatinine (mgm./gm.)	Imidazole nitrogen in non-protein nitrogen (per cent)
	(µmoles/gm. wet tissue)							
Control	2·7	1·0	3·3	5·7	3·8	4·9	0·59	17·0
Histidine-deficient	0·3	0·4	0·4	6·1	3·0	6·0	0·25	12·8
Methionine-deficient	0·4	0·6	0·7	8·2	4·2	7·1	0·31	14·0

large amounts and, as expected in the histidine-deficient fish, there was a decrease in its concentration. The change in carnosine concentration indicates that just as in the case of rats, in which carnosine can liberate histidine, it can replace histidine in the diet[7]. The depleted histidine and carnosine in fish deficient in methionine suggest the possible importance of histidine as a one-carbon donor in fish. In all cases the concentration of anserine remained essentially constant. Since histidine, either through 1-methylhistidine or carnosine, is probably the sole source of anserine, it is rather surprising that the organism, on a histidine-deficient diet, maintains its anserine concentration at a high level. It appears that no demethylating system is available here, just as in the case of the chick (Ousterhout, L., Department of Poultry Husbandry, University of California, personal communication), which, on a histidine-deficient diet, maintains a constant anserine level while histidine and carnosine are progressively depleted. The variation in 1-methylhistidine is explained on the basis of anserinase activity, which has previously been suggested to be present in salmon[4] and which has been demonstrated in cod[8].

Choline-deficient fish from a different experiment were also analysed. Although the results cannot be compared directly, the very high creatine concentration of 11·3 mgm./gm. obtained is noteworthy.

Replacement of Adrenaline and Noradrenaline in the Innervated and Denervated Adrenal Gland of the Rat, following Depletion with Reserpine

IN a previous communication[1] we have shown that reserpine causes a similar percentage loss of adrenaline and noradrenaline from the adrenal gland of the rat. Subsequent recovery of the adrenal amine content was found to be slow. Experiments have now been performed to determine whether this action of reserpine is central or peripheral.

It has been shown by Kroneberg and Schümann[2] that denervation of the adrenal gland of the rat by cutting the spinal cord at the level of *C*6 does not prevent reserpine causing a loss of adrenal catechols. Recently, Mirkin[3] has confirmed this by cutting the splanchnic nerves. However, in both instances the glands have only been assayed for total catechol amines. Here a study has been made of the adrenaline and noradrenaline content of innervated and denervated rat adrenal glands during and subsequent to the depletion caused by reserpine.

The left adrenal glands of male albino rats, weighing 80–100 gm., were denervated by cutting the greater and lesser splanchnic nerve fibres under pentobarbitone sodium anæsthesia—a modification of the method of Vogt[4]. The rats were then left for 3 weeks for the amine content of the glands to return to normal. Test rats were then given 1 mgm./kgm. of reserpine subcutaneously daily for 3 days. Control rats were given the reserpine solvent only. In all experiments test and control groups, each consisting of 10 rats, were killed at 3, 7, 14 and 21 days following the first injection of reserpine, and the adrenal glands removed. The glands were extracted and assayed biologically for adrenaline and noradrenaline, as described earlier[1]. The amine content was expressed in µgm./gland and the points in Fig. 1 represent the percentage difference in amine content between the respective test and control groups.

It can be seen from Fig. 1, derived from the results of three experiments using 300 rats, that there was a similar percentage depletion of adrenaline and noradrenaline, of the order of 40 per cent, in both innervated and denervated glands. The adrenaline then slowly recovered to normal in both groups. However, the noradrenaline content rose to about 200 per cent above the control value at 7 days, falling at 14 days to approximately 80 per cent above, finally returning to normal at 21 days. This occurred in both the innervated and the denervated glands. This similarity between innervated and denervated glands is well seen if the percentages of noradrenaline in the two groups are compared. This is shown at the top of Fig. 1. Before depletion

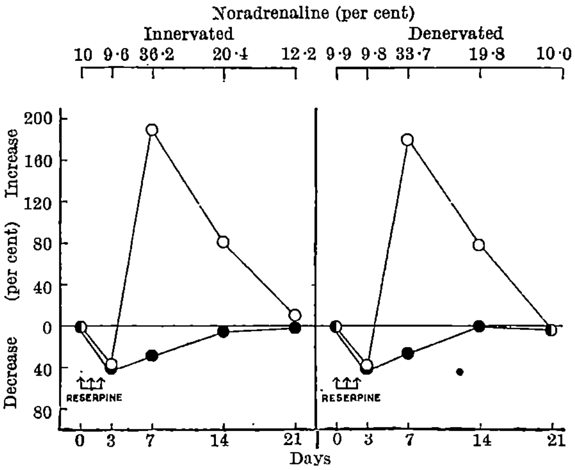

Fig. 1. A composite diagram to show the similarity in the rate of replacement of adrenaline (●) and of noradrenaline (○) in the innervated and denervated adrenal gland of the rat, at various time intervals following depletion with reserpine (1 mgm./kgm.). All results are expressed as percentages of the amine contents of the respective control glands

innervated and denervated glands contain about 10 per cent of noradrenaline. At 3 days, following a similar percentage loss of both adrenaline and noradrenaline, there is still about 10 per cent of noradrenaline present. However, at 7 days both contain about 30 per cent of noradrenaline. This falls to the normal value of 10 per cent by 21 days. Thus no appreciable difference, in either the depletion or replacement of adrenaline and noradrenaline, could be found between innervated and denervated rat adrenal glands. It may be concluded, therefore, that the action of reserpine on the rat adrenal gland is peripheral.

We wish to thank Ciba Laboratories, Ltd., for generous gifts of reserpine.

Mast Cell and Histamine in Rat Anaphylaxis: the Effect of *Haemophilus pertussis*

It is now well established that mice and rats can be rendered hypersensitive to anaphylaxis by inoculation with *Haemophilus pertussis* vaccine, phase I organisms[1]. Treatment with *H. pertussis* also decreases the resistance of mice and rats to several unrelated factors as well as to histamine[1,2] and serotonin[3]. It is also well known that most of the tissue histamine is located in the mast cells[4] and that in rats and mice these cells are also rich in serotonin[5]. The fact that anaphylaxis in the rat produces mast cell damage and release of histamine into plasma[6] led us to investigate the behaviour of these cells in anaphylaxis of rats treated with *H. pertussis*.

White rats (N.I.M.R. strain) of both sexes and weighing between 200 gm. and 250 gm. were used. Two groups of six animals each were studied. One group was injected with 1 ml. of horse serum subcutaneously and the other received 1 ml. of horse serum by the same route plus 1 ml. of *H. pertussis* vaccine containing 20,000 million organisms intraperitoneally. All the animals were challenged 10 days later by injecting 1 ml. of horse serum intravenously under light ether anæsthesia. 5 min. later, 2 ml. of blood was collected, by puncture of the vena cava, in a syringe containing heparin, and the plasma immediately obtained by centrifugation at 0° C. The animals were then killed by bleeding, and the skin of the snout and lips and the tongue were fixed by injecting through the carotid artery a fixative consisting of 50 per cent aqueous ethanol containing 10 per cent formaldehyde and 5 per cent acetic acid. Fixation was allowed to proceed overnight and frozen sections 50μ thick were stained with toluidine blue. The percentage of mast cells showing granule extrusion was determined by counting 500 cells at a magnification of × 160. The plasma histamine content was assayed on the guinea pig ileum.

Table 1. Plasma Histamine Concentration (μgm./ml.) and Mast Cell Disruption (per cent) in Anaphylaxis of Rats treated and untreated with *H. pertussis*

Rat	Disrupted mast cells		Histamine	
	Untreated	Treated with *H. pertussis*	Untreated	Treated with *H. pertussis*
1	0	67	< 0·03	1·9
2	0	44	< 0·03	0·8
3	0	70	< 0·03	1·8
4	0	85	< 0·03	2·0
5	0	38	< 0·03	1·6
6	0	32	< 0·03	0·8

The results of these experiments are shown in Table 1. As can be seen, inoculation with *H. pertussis* enhances the sensitivity to anaphylaxis so that mast cell disruption (the term disruption is here used to describe mast cells presenting granules scattered around the cell without implying damage to the cell membrane) and appearance of histamine in plasma resulted after injection of antigen. The mechanism by which *H. pertussis* inoculation leads to increased sensitivity to anaphylaxis is not yet understood. The increased sensitivity to histamine produced by *pertussis* vaccine does not explain the increased sensitivity to anaphylaxis since it has been shown that sensitivity to anaphylaxis is still present at a time when there is absence of histamine hypersensitivity[7]. The same seems to be the case with the increased sensitivity to serotonin[7]. Since the response of rats treated with *H. pertussis* to several noxious agents is very similar to that presented by adrenalectomized rats[8], the hypothesis has been proposed that *H. pertussis* acts in some way by causing damage to the adrenal glands. Nevertheless, all attempts to demonstrate a direct effect of *H. pertussis* on the adrenal glands have so far failed[7,9]. It is our experience, however, that after anaphylaxis the number of disrupted mast cells in adrenalectomized rats is also larger than in non-adrenalectomized rats, and that this effect can be prevented by treatment with cortisone. Neither adrenalectomy nor *pertussis* inoculation seems to enhance antibody production[9,10].

A possible explanation for the effect both of adrenalectomy and inoculation with *H. pertussis* would be that the tissue cells are more sensitive to the pharmacologically active materials produced as a consequence of the antigen–antibody reaction. However, the fact that hypersensitivity to anaphylaxis does not necessarily co-exist with hypersensitivity to histamine or serotonin, and our present results showing that *H. pertussis* treatment increases mast cell damage and histamine release in anaphylaxis, suggest that it is the effectiveness of the antigen–antibody reaction in directly causing cell damage that is enhanced. The fact that in rats that have not been treated with *H. pertussis* it is also possible to produce mast cell disruption and release of histamine[6] suggests that the effect of inoculation of *H. pertussis* is not a qualitatively new process. Sensitization by the intraperitoneal route is much more effective in producing mast cell disruption and appearance of histamine in plasma in anaphylaxis than sensitization by the subcutaneous route (for example, in a group of rats sensitized by the intraperitoneal route with alum-precipitated bovine serum albumin the average of disrupted mast cells after shock was 32 per cent, while in a similar group injected by the subcutaneous route only it was 0·4 per cent). This difference does not seem to be due to qualitative or quantitative differences in the antibodies produced, but it may be related to the fact that *H. pertussis* is not effective when injected subcutaneously[10]. A comparative study of the effectiveness of the several routes of sensitization in promoting mast cell disruption and histamine release into plasma in anaphylaxis is in progress.

Release of Ammonia by Plant Tissues treated with Indole-3-Acetic Acid

In a previous investigation[1], the uptake of amino-acids by plant tissues was followed by means of radioisotopic techniques. When colorimetric techniques were employed in their stead it was found that uptake was masked by the movement of ninhydrin-positive substances from the tissue into the external solution. This observation led to a study of the release of these substances by plant segments. It was observed that when segments of etiolated hypocotyls of *Helianthus annuus* were floated in water or a solution of indole-3-acetic acid (the range tested was $1 \cdot 1 \times 10^{-5} - 1 \cdot 1 \times 10^{-4} M$) ninhydrin-positive substances rapidly made their appearance in the external medium. The concentration of these substances appeared to reach a maximum value within 2 hr.: continued immersion led to no increase in the ninhydrin colour of the medium but, on the contrary, to its gradual diminution. It was further observed that, while indole-3-acetic acid had no clear-cut influence on the initial loss from the tissue, it had a remarkable effect on the amount of ninhydrin-positive material detectable in the medium after about 20 hr. At this stage the concentration in the media containing the auxin was 2–6 times higher than that in the controls (see Table 1).

The behaviour of the ninhydrin-positive substances did not reflect the permeability of the cell membranes to solutes in general. Flame photometry showed that more potassium had been lost to the surrounding fluid after 20 hr. than after 3 hr., and that the loss was greater in the absence than in the presence of auxin. Similarly, after 20 hr., the aldose and ketose concentrations were if anything somewhat higher in the control media. These findings accorded with the visibly better condition of the auxin-treated segments, which were white and turgid with less tendency to turn brown at the cut ends.

Subsequent investigation by means of filter paper chromatography showed that the ninhydrin-positive material present after 20 hr. and so markedly affected by indole-3-acetic acid was not qualitatively identical with that lost from the tissue during the initial period. That lost initially was found to consist principally of glutamine, asparagine, glutamic acid, aspartic acid, leucine and valine. There is evidence that the disappearance of these substances during the course of the experiment was due not only to uptake by the tissue but also to destruction in the medium by enzymes secreted by the tissue. Indole-3-acetic acid had no appreciable effect on this destruction.

Table 1. THE EFFECT OF INDOLE-3-ACETIC ACID ON THE AMOUNT OF NINHYDRIN-POSITIVE MATERIAL DETECTABLE IN THE MEDIUM SURROUNDING SEGMENTS OF SUNFLOWER HYPOCOTYL

Experiment	Indole-3-acetic acid (concentration in μM)	Fresh weight of segments (mgm.)		Ninhydrin-positive material in medium (colorimeter units*)

The ninhydrin-positive material present after 20-hr. incubation with the segments was only detectable on filter paper if the solution had been acidified prior to concentration and application to the paper. The spot then reacted strongly with Nessler reagent as well as with ninhydrin. The solution before concentration had the following properties: (*a*) it gave an immediate yellow colour with Nessler reagent; (*b*) when mixed with potassium carbonate – potassium bicarbonate buffer, *p*H 9·4, and distilled under reduced pressure in a Parnas apparatus under conditions under which glutamine did not break down, it yielded a distillate which was both Nessler- and ninhydrin-positive; (*c*) when mixed with saturated potassium carbonate and distilled in a Conway microdiffusion apparatus for 3 hr. it yielded an alkaline vapour which could be absorbed in borate buffer. It is thus highly probable that the substance under investigation was ammonia (it will be referred to as such below) though this has not been conclusively proved. It might, for example, be an exceedingly labile substance (considerably more labile than glutamine) readily breaking down to give ammonia. The influence of indole-3-acetic acid could be clearly followed by all of the analytical methods listed under (*a*), (*b*) and (*c*) above.

The work so far described was carried out with seedlings of the variety Pole Star which had been grown in the dark at 24° C. for 7 days. Segments 1 cm. long were cut from the hypocotyls at a distance of 1 cm. below the crook and floated in shallow layers of solution contained in large, stoppered flasks which were shaken gently throughout the experiment. When a change was made to a new batch of seeds from a different supplier, difficulty was at first experienced in reproducing the auxin

effect. It was then found that the effect was readily demonstrable either if the plants were allowed to grow for a further three days before removal of the segments, or if the segments themselves were 'aged' by continued immersion in the experimental solutions. These observations suggested that the appearance of ammonia might be due to the utilization of amino-acids as a substrate in respiration (cf. Yemm[2]) and that this process only started after some other substrate had been exhausted, which in the case of the new seeds required more time. Attempts were therefore made in further experiments (carried out with the variety Jupiter) to counter the auxin-stimulated production of ammonia by the provision of an alternative respiratory substrate. Table 2 shows that the addition of either succinate or sucrose prevented the accumulation of ammonia in the media containing the auxin.

If ammonia production was in fact reflecting the respiration of amino-acids it is of importance to note that indole-3-acetic acid did not bring about a stimulation in overall respiration-rate comparable in magnitude with that effected in ammonia production. The oxygen uptake of auxin-treated tissue was at no stage of the experiment more than 25 per cent above that of the controls. The stimulation in ammonia production, on the other hand, was of the order of 200 per cent. This would indicate that in the auxin-treated tissue amino-acids formed a larger proportion of the substrate respired, and may imply a connexion between the action of auxin and the respiration of amino-acids. This suggestion was made previously[3] on entirely different grounds, namely, the higher specific activity of the carbon dioxide evolved by auxin-treated, as compared with control, segments when radioactive glutamic acid was supplied in the external solution. Another possible explanation for the higher proportion of amino-acids apparently respired in the presence of indole-3-acetic acid is that the increased cell-wall synthesis stimulated by the auxin consumes alternative respiratory substrates such as sugars.

The disappearance of the auxin effect in the presence of succinic acid or sucrose does not necessarily indicate, however, that these substances were suppressing the oxidation of amino-acids. They may have provided acceptor molecules for the ammonia produced in processes other than oxidation. It is possible, for example, that the release of ammonia observed in media containing auxin was connected, not with respiration, but with protein synthesis. A preliminary to the latter might be the hydrolysis of glutamine and asparagine, considerable reserves of which are known to be present in this tissue.

The effect of indole-3-acetic acid reported here is not confined to sunflower tissue. It has also been noted in the epicotyls of *Pisum sativum* var. Alaska, though the effect has not yet been investigated further in this case.

This work will be published in detail elsewhere.

I wish to express my appreciation of the encouragement given me by Prof. G. E. Blackman, director of this Unit.

Presence in Root Tips of a Thermolabile Factor causing the Conversion of Protochlorophyll to a Leuco-Compound

IN a previous paper[1], it was reported that protochlorophyll occurs in the tips of dark-grown roots. It was also shown that protochlorophyll disappears immediately after living root tips have been squashed. It also disappears from raw ether extracts during the evaporation of the ether. This implies that neither the pulp from squashed tips nor the watery residue dissolved in ether exhibits any red fluorescence. I have now succeeded in demonstrating that some thermolabile factor is responsible for this destruction of protochlorophyll.

To prepare an extract containing this factor, about 5 gm. of fresh root tips (apical part of root, about 0·5 cm. in length) from seedlings grown in 'Vermiculite' moistened with the nutrient solution were ground with sand in a mortar with 20 ml. of ether. The ether solution was decanted and used as a source of the factor. To activate this factor, however, it was necessary to remove the ether from the extract. Extracts from root tips of both *Zea mays* and *Helianthus annus* were tested.

The protochlorophyll was prepared as a raw extract from dark-grown wheat leaves according to Virgin[2], but in some series the leaves were first killed by immersion in water at 100° C. for 10 min. The following procedure was then used to determine the activity of the factor. 1 ml. of the extract from the root tips was put into an Erlenmeyer flask together with two drops of distilled water, and the ether was removed by evaporation *in vacuo*. The concentrated aqueous extract was kept for 10 min. at temperatures of 20° C. or at 100° C. (water-bath). 4 ml. of the protochlorophyll extract were then added and the ether removed. As a second evaporation increased the effect of the factor, 4 ml. of the ether were added to the aqueous residue after 2 min. at 20° C. and the ether was again removed. The extract was then diluted with 4 ml. of ether and its absorption in red light was determined spectrophotometrically by means of a Beckman spectrophotometer model *DU*. The fluorescence was estimated visually[1].

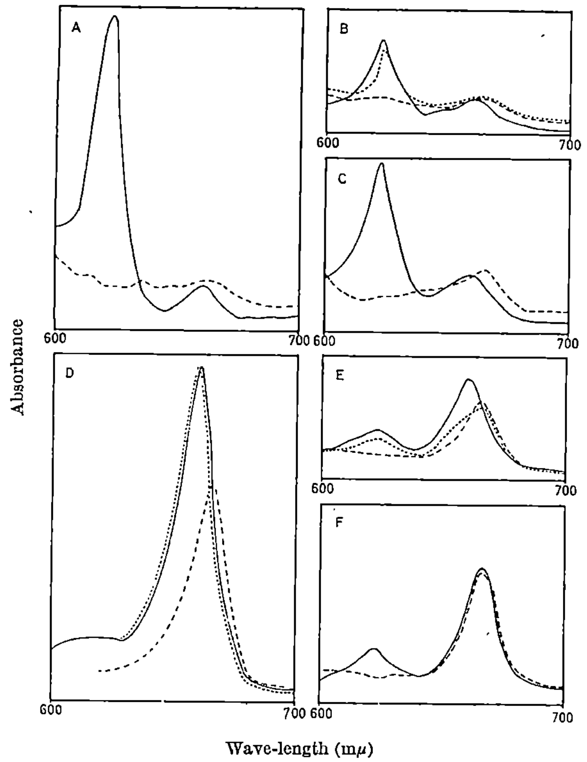

Fig. 1. Absorption of the different samples. ——, Initial absorption of the sample; ...., absorption after evaporation procedure without active factor; ----, absorption after test procedure with the active factor from root tips of *Zea* (*A*,*F*) and of *Helianthus* (*B*,*C*,*D*,*E*). *A*,*B*,*C*, samples containing protochlorophyll together with very small amounts of chlorophyll *a* (contamination due to imperfect green light during extraction). *D*,*E*, extracts containing chlorophyll *a* resulting from light transformation of protochlorophyll. Small amounts of non-transformed protochlorophyll present in *E* (crude extract) but not in *D* (purified extract). *F*, solution of purified pheophytin *a* in a mixture with raw extract of protochlorophyll

The results (Table 1, Fig. 1) indicate the following: the root-tip extract contains a factor which causes decomposition of protochlorophyll into a compound without red light absorption. When protochlorophyll was the only red fluorescing substance in the solution (without chlorophyll), the red fluorescence disappeared completely. This indicates that the product of decomposition is not protopheophytin, since if this were the case the solution ought to give a distinct red fluorescence[3]. The activity of the factor is destroyed by heating. The susceptibility to heating indicates that it may be associated with a protein (an enzyme ?).

Table 1. Absorption of the Test Solutions at the Point of Maximum of Red Absorption of Protochlorophyll (623 mμ). The red fluorescence determined visually according to the method earlier described (ref. 1) is given below the figures for the absorption. The values are the means from three determinations

Sample	Initially	Ether removed by evaporation and new ether added		
		Without root tip extract	Root tip extract added: at 20° C.	Root tip extract added: heated to 100° C. for 10 min.
Protochlorophyll from dark-grown wheat leaves. Root tip extract from *Zea mays*	0·013 strong	0·012 strong	0·005 none	0·013 strong
Protochlorophyll from dark-grown wheat leaves (also containing small amounts of chlorophyll *a*) (cf. Fig. 1*B*). Root tip extract from *Helianthus*	0·320 strong	0·032 strong	0·013 weak	0·033 strong
As above, but leaves were killed with hot water before extraction	0·012 strong	0·012 strong	0·005 none	0·013 strong

To determine whether this compound also acts on chlorophyll, etiolated leaves, before extraction, were illuminated for 10 min. with daylight in order to transform part of the protochlorophyll to chlorophyll *a*. It was found, however, that the evaporation of the ether from the raw extract resulted in a conversion of chlorophyll *a* into pheophytin *a*, independently of the presence of the factor in question (Fig. 1*B*). Chlorophyll purified on a saccharose column and dissolved in ether was unchanged during the evaporation of the ether. It was transformed to pheophytin, however, when a small amount of the extract from the root tips was added to the solution even when the extract had been previously heated (Fig. 1*D*). This means that the transformation of chlorophyll *a* into pheophytin *a* is not dependent on the factor in question but is rather due to some acidic impurities present in the extract.

To determine whether the factor exerts any effect on pheophytin *a*, pure pheophytin in ether solution alone and combined with a raw protochlorophyll extract were tested with the same procedure as used for protochlorophyll. One example is given in Fig. 1*F*. It can be seen that the factor has no influence on pheophytin.

The protochlorophyll in raw extract from etiolated wheat leaves mixed with an ether extract from root tips is fairly stable so long as the ether is not removed by evaporation. Since the evaporation of the ether from the extract resulted in an increase of the concentration of water, one may assume that the increased water content is responsible for the activation of the factor. The method of extraction of root tips with ether was employed only for its convenience in the test procedure. The factor probably dissolves in ether along with water and other substances, but to be active it requires a higher concentration of water than is present in the non-evaporated ether extract. The factor is not stable in the ether extract. Its activity disappears after two to three weeks at 0° C.

An Observed 'Oxygen Effect' during Gamma-irradiation of Dried Bacterial Spores

On numerous occasions it has been shown that changes produced in aqueous biological systems by exposure to ionizing radiations of low specific ionization can be influenced by environmental conditions during irradiation. Since it is considered that environmental conditions affect the types and yields of free radicals formed on irradiation of water, the suggestion has been made that the observed biological changes are induced mainly by indirect action. Recent observations on irradiated non-aqueous synthetic macromolecular systems and on dry isolated cellular constituents have shown that changes produced by direct action can also be influenced by environmental

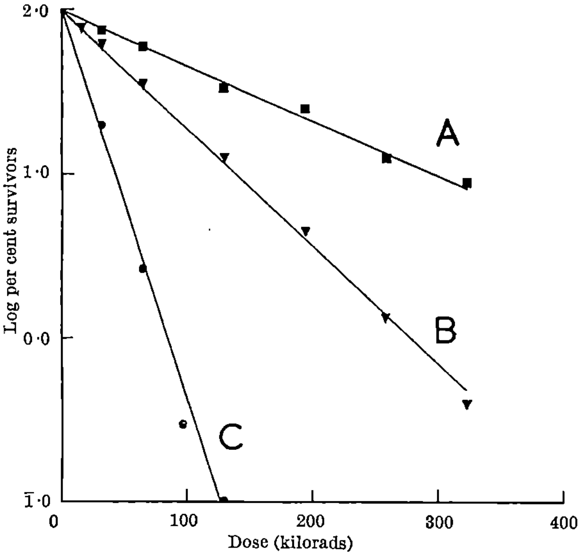

Fig. 1. γ-Irradiation of *B. subtilis* spores in kaolin powders sealed under reduced pressure and under air. *A*, secondary dried powder under reduced pressure; *B*, primary dried powder under air; *C*, secondary dried powder under air

conditions[1-3]. Alexander[4] has therefore postulated that direct action may cause changes in biological systems in cases where, in the past, it was thought that indirect action was responsible. However, alteration of the environmental conditions in circumstances where only direct action is known to be operative has not yet been shown to influence the lethal action of ionizing radiations on bacterial cells.

During a series of experiments involving γ-irradiation of spores of *Bacillus subtilis*, which had been dried in atmospheres of low aqueous vapour pressure, it has been observed that the presence of oxygen during irradiation influences their survival.

A powder, known to contain *B. subtilis* spores evenly distributed throughout it, was prepared by spray-drying a mixed aqueous suspension of kaolin and spores[5]. This is referred to as a primary dried powder. Glass tubes containing samples of known weights of this primary dried powder were attached to a glass manifold which in turn was connected to a two-stage rotary vacuum pump via a refrigerated moisture trap. Using this apparatus, the samples of primary dried kaolin powder were further dried for 6 hr. at a pressure of 0·001 mm. of mercury with liquid nitrogen as refrigerant. The powder dried in this way is referred to as a secondary dried powder. At the end of the secondary drying period, some of the samples of powder were sealed under reduced pressure (0·001 mm. of mercury) while others were sealed under air which had first passed through the moisture trap. Dose/log per cent survivor curves obtained from the γ-irradiation of spores in secondary dried kaolin powder sealed under reduced pressure and sealed under air, and the curve obtained from the irradiation of spores in primary dried powder sealed under air, are given in Fig. 1. The criterion of survival adopted was the ability of spores to produce colonies when sown into nutrient agar medium.

The low free-water content of bacterial spores[6,7] and the extreme drying conditions to which they are subjected during secondary drying probably ensure that killing of the spores on γ-irradiation occurs as a result of direct action. A comparison of curves *A* and *C* shows that the presence of air during irradiation greatly increases the kill of spores in secondary dried kaolin powder. This finding indicates that the observation of an 'oxygen effect' during irradiation of bacterial cells cannot be taken as evidence that indirect mechanisms are operative.

Comparison of curves *B* and *C* shows that spores in secondary dried kaolin powder, irradiated in the presence of air, are more sensitive to γ-radiation than spores in primary dried kaolin powder irradiated in the presence of air. This finding is of particular interest since the observed inverse relationship between moisture content and radiosensitivity is contrary to what would be expected from a consideration of the more usually reported protective effect resulting from dehydration of living cells. Further results from this series of experiments will be published elsewhere.

Absence of Pectolytic Enzymes in a Pathogenic Strain of *Fusarium oxysporum* f. *lycopersici*

THE pectic enzymes produced by *Fusarium oxysporum* Schl. emend. Sny. and Han. f. *lycopersici* (Sacc.) Sny. and Han. have been considered to play an important part in the production of symptoms and of wilting in tomato plants infected with *Fusarium*[1]. It has been suggested that pectic enzymes are not responsible for the full range of symptoms[2,3] and that other metabolites may be involved. The pectic enzymes have also been considered important for the invasion of a wide range of plants by fungal parasites[2].

During the course of an investigation of the pectic enzymes of *Fusarium oxysporum* f. *lycopersici* an attempt was made to produce mutants which lacked pectic enzymes. The mutants were obtained by subjecting microconidia of strain *R*-5-6 (obtained from Prof. J. C. Walker, Wisconsin) to ultra-violet irradiation and a subsequent screening procedure. The usual method for isolating biochemically deficient mutants was reversed, the irradiated conidia being first plated out on a minimal medium (glucose-minerals) to eliminate any nutritionally deficient mutants. The colonies, arising from single microconidia, which developed on the minimal medium were screened over plates of pectin (B.D.H. 'Apple Pectin' Grade 240) agar and of pectate (sodium polypectate, California Fruit Growers Exchange) gel[4], and those which obviously differed in rate of growth from the wild type were selected for further study. The pectin and sodium polypectate used in the preparation of the screening media contained traces of glucose which facilitated at least limited growth of all survivors. A number of mutants were thus selected and their abilities to produce pectic enzymes and their pathogenicities were investigated under standard conditions.

The pectic enzyme activities of pectin–agar plate cultures and of liquid culture filtrates were estimated by modifications of the cup-plate assay method[5]. It was during these investigations that mutant strain 80, which produced no pectolytic enzyme, but which produced pectin methyl esterase, was found. This was afterwards confirmed using the Willstäter–Schudel hypoiodite method for polygalacturonase and the viscometric method for depolymerase.

Strain 80 was moderately pathogenic in the susceptible tomato variety Kondine Red either when seedlings were root inoculated or when cuttings were inoculated by the transpirational method[6]. The symptoms produced included petiole epinasty, some leaf yellowing and shrivelling, vascular browning, and vascular plugging. However, symptoms of more severe disease, such as severe wilting and collapse of the leaves and death of the plant, as might be seen in those plants inoculated with the wild type, *R*–5–6, were never apparent. The pathogenicity measurements were made with batches of twenty plants inoculated with each strain, under conditions which were optimal for disease development.

It is possible that the mutation (in strain 80) is one leading to a requirement for some specific substance for pectolytic enzyme synthesis and that this substance is available to some extent in the host tissues. If this is not the case, it can be concluded that pectolytic enzyme production is not necessary for the successful establishment of *F. oxysporum.* f. *lycopersici* in the host plant and that the pectolytic enzymes play no part in the production of symptoms in moderately diseased plants.

This work, the full details of which will be published elsewhere, has been carried out during the tenure of an Agricultural Research Council Research Studentship. I am indebted to Dr. N. F. Robertson under whose supervision the investigations were made.

Initial Irradiation Reaction in Mice

EXPOSURE of the whole body to large doses of ionizing radiations produces an immediate effect in primates. In man the absorption of 500 r. of X-rays or γ-rays causes a sensation of lassitude, often accompanied by nausea and vomiting. In atomic-bomb casualties in Nagasaki and Hiroshima these symptoms developed[1,2] from one-half to several hours after exposure. The duration of the symptoms was short, ranging from a few hours to two days.

A similar reaction has recently been observed in monkeys. Hunter *et al.*[3] have reported that the behaviour of *M. mulatta* monkeys exposed to 450 r. of whole-body cobalt-60 γ-radiation changed shortly after irradiation. The activity of the animals was greatly diminished; they would sit quietly in a corner or lie down on the floor of the cage. This was accompanied in most animals by retching and vomiting.

In the course of various irradiation experiments we have observed a behavioural change in mice which is similar in some respects to the initial reaction occurring in man and monkeys. During the absorption of large doses of X-irradiation the mice quite suddenly became inactive. Most of them sprawled motionless on the floor of the cage with their hind limbs extended backwards. The mice in this inactive state seemed to respond normally to external stimuli such as noise and painful pressure on their tails. The duration of inactivity lasted from 5 to 30 min. after exposure.

We have termed the amount of total body irradiation which is required to bring about inactivation in mice, the 'inactivation dose'. In the present study we measured the inactivation dose in a number of mice to determine with what degree of constancy the phenomenon occurred; we also irradiated mice of different age groups to determine whether age had any effect on inactivation.

Forty-seven adult male white mice (Connaught Laboratory strain) were arranged in three age groups, namely, 2, 3½ and 4½ months. No animal received more than the amount of irradiation required to produce inactivation. All animals were observed for 30 days, and the deaths which occurred were recorded. A Ferranti (*RV*–220) therapy unit was used. The radiation factors were as follows: operating voltage, 200 kV.; tube current, 20 m.amp.; H.V.L., 1·55 mm. of copper. The animals were irradiated at a distance of 40 cm., which produced a dose rate in air of 48 r./min. In order to determine the time of inactivation with more accuracy than by visual observation, the following simple movement-recording device was used. The mouse was placed in a small wire cage which rested on a wooden platform under the X-ray beam. The platform was supported by four light coil springs, one in each corner. A piezo-electric crystal (recording cartridge) was attached to the side of the platform by its stylus and allowed to hang freely. In this manner the movements of the platform, made by the mouse, were transmitted to the crystal in which piezo-electric currents were produced. These electrical impulses were amplified and recorded on an ink-writing recorder (Varian Associates, Palo Alto, California). The X-ray unit

Table 1. THE RANGE AND AVERAGE VALUES OF THE INACTIVATION DOSE IN MICE OF DIFFERENT AGE GROUPS

	No. of animals	Average weight of animals (gm.)	Inactivation dose (r.)		*P*	No. of deaths	Mortality (per cent)
			Range	Av. S.E.			
2-month old mice	20	21·3	400–800	604 ± 26		11	55
3½-month old mice	20	27·6	375–725	512 ± 23	0·02	7	35
4½-month old mice	7	34·4	400–650	503 ± 32	0·05	0	0

was turned off when cessation of movement was noted and a permanent record was obtained.

The results are shown in Table 1. It will be noted that the dose required for inactivation decreases as the age of the animal increases. 2-month, 3½-month and 4½-month groups of mice showed average inactivation doses of 604 r., 512 r. and 503 r., respectively. The latter two values were both statistically different from the first value. 55 per cent of the youngest animals died when exposed to the dose required to produce inactivation, compared with 35 per cent deaths in the 3½-month group and no deaths in the 4½-month group.

There is considerable evidence[4] that age decreases the sensitivity of animals to irradiation. Older animals require more irradiation than younger animals to produce comparable degrees of leukopœnia, anæmia or lethality. It is, however, evident that the inactivation phenomenon does not follow the dosage relationship in this manner. If it did, we would expect to find that older animals required a greater amount of irradiation to produce inactivation than the younger animals. Our results show the reverse to be true, which suggests that the nature of inactivation is different from the other manifestations of irradiation injury.

Corneo-Fundal Potential Variations during Light and Dark Adaptation

THE corneo-fundal potential (that is, the steady potential difference across the eye) was discovered in 1849 by Du Bois-Reymond[1]. Noell[2] has recently shown evidence that a part of the corneo-fundal potential is attributable to the membrane polarization of the pigment epithelium adjacent to the sensory cells of the retina. He found, while measuring the retinogram in rabbits, polarization changes lasting for more than 200 sec. following the onset of illumination. An analogous phenomenon, described in detail below, occurs in humans.

The surface-potential differences obtained from electrodes placed on the skin near the eyes (outer canthi) were shown by Mowrer, Ruch and Miller[3], in animals, to be related to the electrical polarization (cornea positive with respect to fundus) of the eye-bulb.

A method of surface-recording similar to that used by Miles[4] for studies of individual differences in humans was modified by Kris[5], giving the results described here.

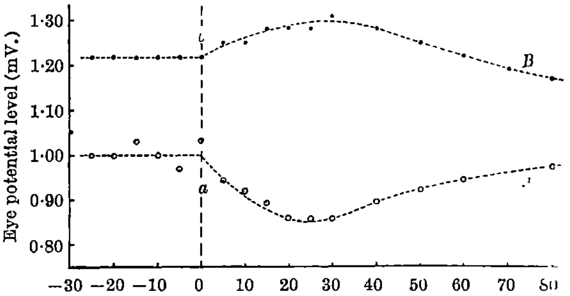

Fig. 1. Curves of variation of eye potential-level changes at onset of (○ – – ○) light adaptation, and (● – – ●) dark adaptation. *a*, Light on; *b*, light off. Measurements taken from left eye *D*–*C* horizontal record of subject *SS*, sections 1_1 and 1_{14}

When the eye has been adapted either to light or dark, a step-change in illumination produces an initial transient effect lasting between 60 and 80 sec., as shown in Fig. 1.

For light-adaptation, the initial transient dip (curve *A*) is followed by a fluctuation resembling a damped oscillation of 30 min. period, lasting approximately one hour (Fig. 2). The peak and trough times observed in 18 complete light-adaptations by six subjects fell within the following ranges: 1st peak at 10th min. ± 2 min.; 1st trough at 25th min. ± 4 min.; 2nd peak at 36th min. ± 4 min. These variations include the diurnal variations of three subjects who were adapted repeatedly over a 30 hr. test-period[6]. One subject, who did not show initial transients, reported red-green colour-blindness. While the pattern of fluctuation was the same for light-adaptations to illumination intensities of 7 and 140 millilamberts, the amplitude of fluctuation was higher with the higher level of illumination (Fig. 2, *a* and *c*).

For dark-adaptation following complete light-adaptation, the initial transient rise (Fig. 1, curve *B*) is followed by a fall in potential-level over the first 8–10 min., and then by a gradual rise (taking approximately 20 min.) to a steady-state level which is regularly somewhat lower than that of the light-adapted steady-state level. See Fig. 2, section *b*, which shows the first 20 min. of a dark-adaptation curve.

The presence of a damped oscillation suggests a homœostatic mechanism.

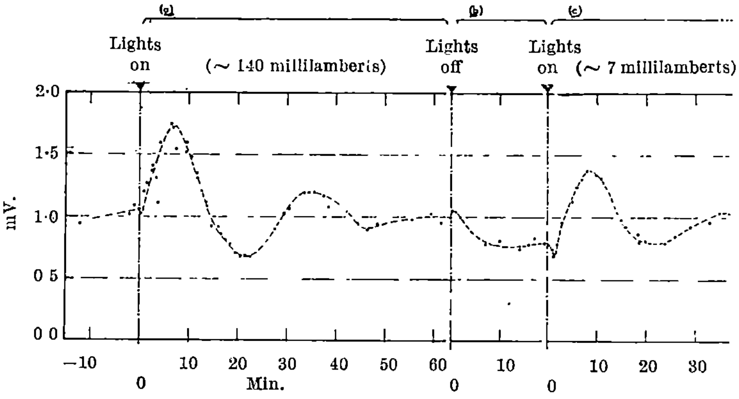

Fig. 2. Changes in eye potential-level during adaptation successively to (*a*) strong illumination; (*b*) darkness; (*c*) moderate illumination. Subject: *RS*. Ordinates: change in potential across electrode-pair lateral and mesial to left eye, produced by standard 60° horizontal fixation shifts

This work was done with the help of Mr. A. Atkin, research assistant, under Contract *AF* 33(616)–3849 (1957) between the Aero-Medical Laboratory, Wright Air Development Command, and the Massachusetts Institute of Technology.

A Water-soluble, Diffusible Pigment produced by a Strain of *Serratia marcescens* (*Chromobacterium prodigiosum*)

Members of the bacterial species, *Serratia marcescens*, are characterized by the production of red or pink pigments. These pigments are described as being insoluble, or sparingly soluble in water, and to be associated with the bacterial cell[1,2]. Heavily pigmented strains show some diffusion of pigment into agar media, but the organisms still retain most of the colour[2,3]. We wish to report a red-to-pink pigment produced by a strain of *S. marcescens* which not only is readily soluble in water, but which also diffuses from the organisms into the medium and leaves the cells colourless.

S. marcescens strain 125 was received from Dr. L. S. McClung of the Department of Bacteriology, Indiana University, Bloomington. The strain had been identified as *S. marcescens* by Hamilton[4]. Tests carried out in our laboratory demonstrated that the organism was a small, motile, cocco-bacillary, Gram-negative rod. It fermented glucose, mannitol, and sucrose without the production of gas. Lactose and maltose were not fermented. The citrate and nitrate tests were positive, but those for hydrogen sulphide production, indole, and urease were negative. Gelatin was liquefied. With the exception of the failure to ferment maltose, these characteristics are those of *S. marcescens* organisms as presented in authoritative sources[1,2,4,5]. Electron microscopy showed the presence of peritrichous flagella. The organism did not produce pigment when cultivated at 37° C.

For pigment production, strain 125 was grown in 5-l. Povitsky toxin bottles containing 1 l. of casein hydrolysate–yeast extract–agar medium[6]. The cultures were grown for 5 days at 27° C. The colourless cells were scraped from the agar surface and discarded. The agar was homogenized in a high-speed blendor, and then washed continuously on a Buchner funnel with distilled water until the maximum amount of pigment had been extracted. The pigment was adsorbed from the filtrate on to activated charcoal ('Darco *G*–60', Atlas Power Co.), and after adsorption the charcoal was washed several times with distilled water. The pigment was eluted with glacial acetic acid, dried *in vacuo*, and the residue dissolved in a small amount of distilled water. Since the pigment is insoluble in petroleum ether this solvent was used for washing the water solution several times to remove contaminating substances. Final purification of the pigment was effected by continuous paper electrophoresis in 5 per cent acetic acid on a 'Spinco' Model *CP* unit. The pigment moved as a single band, and all of it was collected in only two tubes. Acetic acid was removed from the eluate by drying *in vacuo*, and washing the dried material several times with petroleum ether. The pigment was then dissolved in a small amount of distilled water, lyophilized, and stored as the dry substance.

The purified pigment was red to pink in colour, and was insoluble in acetone, chloroform, ether and petroleum ether, but was soluble in ethanol, methanol, and water. In solvent systems composed of lutidine and water (5 : 3), and *iso*propanol, concentrated hydrochloric acid and water (65 : 16·6 : 18·4) the pigment moved as a single band. The bands showed no fluorescence under short or long wave-length ultra-violet light. Paper electrophoresis demonstrated that the pigment moved as a single substance in barbiturate buffer, *p*H 8·6, as well as in acetic acid. The isoelectric point in acetate buffer was *p*H 3·5. After combustion of material eluted from chromatograms, there still remained considerable ash. Therefore chemical analysis of the pigment must await more complete purification. Efforts to crystallize the pigment have thus far failed. The acid, base and neutral spectra of the pigment are presented in Fig. 1. The spectral maxima are at 550 and 280 mμ, and the minimum is at 425 mμ. These values do not vary with changes in *p*H, although the shape of the curves is somewhat modified.

To our knowledge this is the first time a water-soluble, diffusible pigment of *S. marcescens* has been

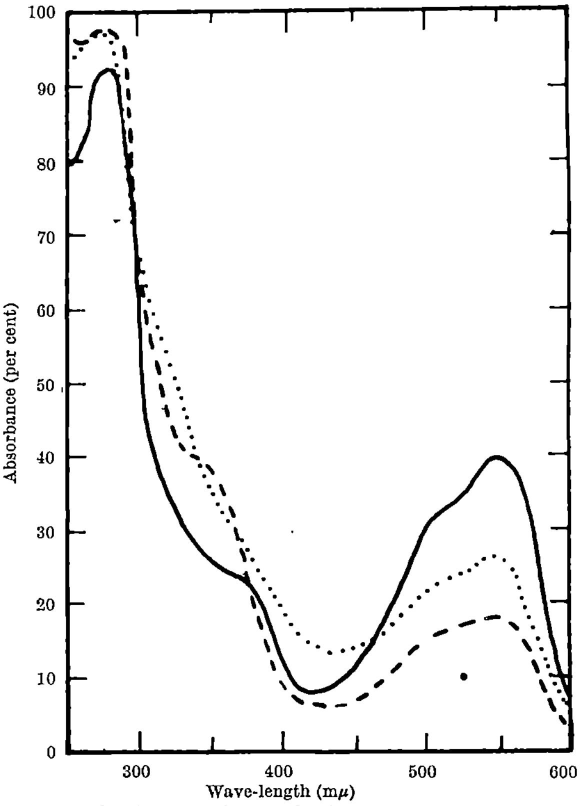

Fig. 1. Spectra of water-soluble, diffusible pigment from *S. marcescens*. ––– in acid, *p*H 4 ; . . . in alkali, *p*H 9 ; —— in neutral solution. All spectral determinations were carried out in water solutions

reported. The biochemical tests establish the fact that strain 125 is *S. marcescens*, and the presence of peritrichous flagella, as well as the fermentation reactions, indicate that the organism cannot belong to the pseudomonad group. It has been pointed out that *Serratia* organisms can vary widely in their ability to produce pigment, and in the colour of the pigment[1,2]. Thus it should not be surprising to find that certain strains produce a diffusible, rather than a cellular, pigment.

It is of interest to compare certain properties of extracted cellular pigment with those of diffusible pigment. In contrast to the latter substance, cellular pigment is insoluble in water, but readily soluble in acetone, chloroform, ether and petroleum ether[6]. It cannot be moved by paper electrophoresis. Both pigments are red in colour, but the diffusible pigment is of a lighter shade. The spectrum of the cellular pigment shows marked shifts with variation in *p*H, and the maximum peaks in acid solution are at 540, 375 and 275 $m\mu$, and the minima, at 420 and 330 $m\mu$ [6]. As can be seen in Fig. 1, the spectrum of diffusible pigment shows little variation with changes in *p*H, and although the acid curve has maxima and minima similar to those of cellular pigment, the two spectra are not identical. Cellular pigment also can be separated into several fractions[6], whereas diffusible pigment appears to be a single substance. Thus with respect to the above characteristics, there are marked differences between cellular and diffusible pigment. Whether there are any relationships in chemical structure between the two pigments must await further investigations.

This investigation was supported in part by research grant *E*-670(C3), and in part by a Medical Student Summer Research Fellowship to one of us (W. W. T.), both from the National Institutes of Health, U.S. Public Health Service.

Serum Protein Variations in Horses

It is now clear that intraspecific serum protein variation is widespread in mammals at least, and that the technique of starch-gel electrophoresis developed by Smithies[1] is a powerful tool for revealing these differences. Complex protein patterns have been obtained with sera from horses, due to concomitant variation in several protein systems.

Sera from 79 thoroughbred and other ('knacker') horses of unspecified breed were examined, using *p*H 7·6 phosphate buffer and electrolyte as described previously[2]. Four variable systems were found, namely, the β-globulins, pre-albumins and two apparently unrelated α-globulin systems. Electropherograms of three sera illustrating these variations are shown in Fig. 1. A diagram of a two-dimensional agar/starch-gel electropherogram[2] of another serum is shown in Fig. 2.

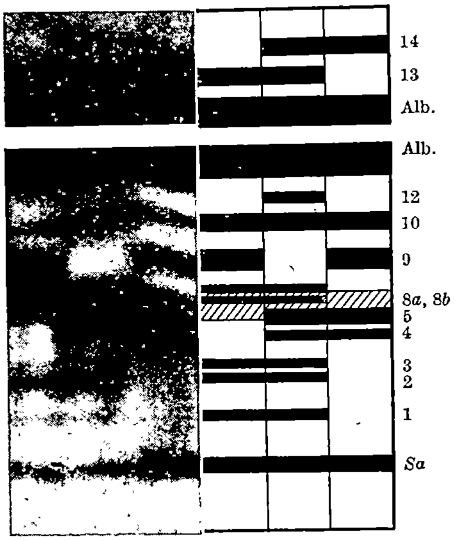

Fig. 1. Starch gel electrophoresis protein patterns from three representative horse sera. Only the anodic side of the gel is illustrated. The main part of the gel was from a 5-hr. run at 200 V.; the pre-albumin portion was from a separate 3-hr. run at the same voltage. Alb., albumin; *Sa*, slow-alpha globulins; 1–6, β-globulins; 8*a*, 8*b* and 9, first variable α-globulins; 12, second variable α-globulin; 13 and 14, pre-albumins. Zone 7 (cross-hatched) is usually rather diffuse and occurs in the region of zones 5, 6 and 8

Three β-globulin types were observed. It is possible that these represent the homozygotes and heterozygote of two β-globulin alleles, one producing zones 1, 2 and 3 and the other zones 4, 5 and 6. This would be comparable with previously described β-globulin systems in other species[3].

Three types have been found in the first of the variable α-globulin systems depending on the presence of either or both zones 8 and 9. In some gels zone 8 is resolved into two zones, 8*a* and 8*b*, but neither of these has so far been found alone. The α-globulin zone 7 is apparently always present but is not sharply defined. In one-dimensional runs it appears in the

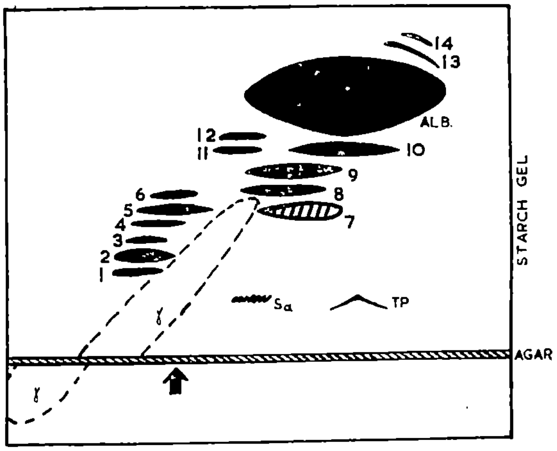

Fig. 2. Diagram of a two-dimensional electropherogram of a selected horse serum. The arrow indicates the position of insertion of the original sample in the agar. γ, γ-globulins; *TP*, thread protein. See also key to Fig. 1

region of zones 5, 6 and 8 as a diffuse band. Experiments with added hæmoglobin suggest that this may be the hæmoglobin-binding protein (haptoglobin).

The second variable α-globulin system has shown two types depending on the presence or absence of zone 12. The distinction between these types is not always easy in one-dimensional runs, but is made more readily in two-dimensional separations.

At least three pre-albumin types have been observed in the sera examined, depending on the presence of either or both zones 13 and 14. However, a third pre-albumin zone, intermediate in mobility to the other two, has been seen in two sera, but only in the absence of zone 14.

It will be necessary to examine an appropriate number of related individuals to determine if these variations are inherited, that is, constitute further examples of serum protein polymorphism.

I thank Mr. A. Thomson, of the Wellcome Research Laboratories, and the staff of the Equine Research Station of the Animal Health Trust for providing horse sera, and K. F. Mitchell for technical assistance.

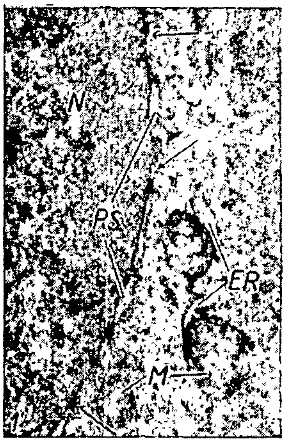
Fine Structure of the Nuclear Envelope of Carcinoma Cells

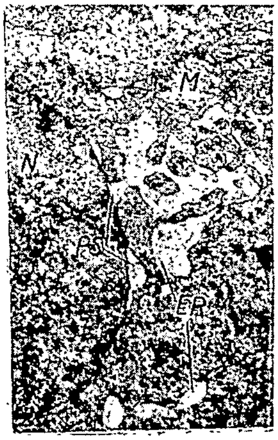
Palade[1] was the first to observe with the electron microscope that the plasma membrane forms invaginations which occasionally plunge deeply into the cell body. He has shown that the lumen of the infoldings of the cell membrane communicates with the interior of the endoplasmic reticulum. Watson[2] showed that in certain cells the outer nuclear membrane is continuous with the membrane system of Palade's reticulum. Therefore, his 'perinuclear space' is part and parcel of the cavities of the endoplasmic reticulum. By demonstrating that the inner and outer nuclear membranes fuse at the edges of the nuclear pore, Watson[2] suggested that the nuclear envelope is simply a specialized form of endoplasmic reticulum.

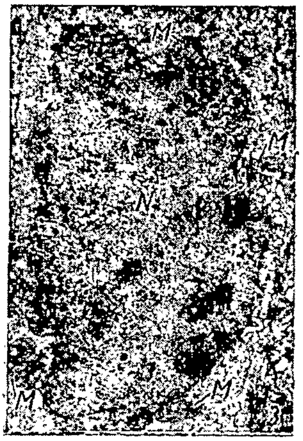
Those considerations about the continuity of the lumen of the endoplasmic reticulum and the perinuclear cisterna are based on electron micrographs of acinar cells of the pancreas, of parenchymatous liver cells and phagocytes and of Rous tumour cells[3]. It was suggested that a relation exists between the magnitude of such structures and the type of activity of the cell under consideration.

During morphological work on cells of chemically induced carcinoma of the cervix uteri of mice, electron micrographs were obtained in which structural details of the nuclear envelope were found to be strikingly similar to those mentioned above. The existence of a double nuclear membrane is shown in Figs. 1 and 3. In some of the carcinoma cells (Fig. 2) the outer nuclear membrane appears to be lifted up and continuous with the endoplasmic reticulum. Moreover, the portion of the endoplasmic reticulum with a rough surface is highly developed and the cytoplasmic matrix of this cancer cell is reduced to narrow strands lying between the swollen cavities of the reticular system (Fig. 2).

Many of the malignant cells show several nuclear indentations, a fact sufficiently known from light microscopy. The electron microscope clearly shows that both the outer and inner nuclear membranes participate to the formation of true nuclear infoldings







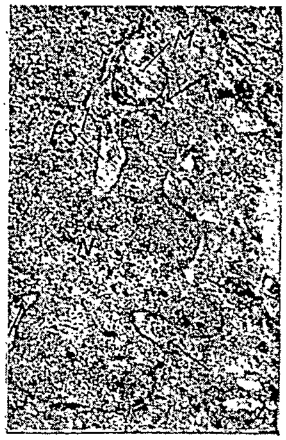


Fig. 1. Electron micrograph of a portion of a nucleus (*N*) and adjoining cytoplasm of a cancer cell. The two layers of the nuclear envelope and the perinuclear space between them (*PS*) are apparent. Nuclear pores are indicated by the arrows. Near the nuclear envelope the cytoplasm contains several mitochondria (*M*) and profiles of rough-surfaced membranes of the endoplasmic reticulum (*ER*). (× 38,000)

Fig. 2. Electron micrograph of another cancer cell from the same tissue as Fig. 1. The granular nucleus (*N*) occupies the left part of the picture. The outer nuclear membrane is reflected into the cytoplasm in such a way that the perinuclear space (*PS*) is clearly continuous with the interior of the labyrinth of the endoplasmic reticulum (*ER*). At the upper left corner another nucleus also bounded by a double nuclear membrane. (× 29,500)

Fig. 3. Electron micrograph of a nucleus (*N*) of another cancer cell from the same tissue as Figs. 1 and 2. Between the double nuclear membrane the perinuclear cisterna is apparent (arrows). A great number of mitochondria (*M*) are closely associated with the depressions of the nuclear envelope. (× 20,000)

Fig. 4. Electron micrograph of a part of another cancer cell of the same tissue as Figs. 1, 2 and 3. The granular nucleus (*N*) shows several deep indentations (arrows). At *PS* the perinuclear space is seen between the inner and the outer nuclear membrane. A mitochondrion (*M*) lies as if waiting for the contents of the indentation. (× 32,000)

(Fig. 4). While the perinuclear space contained within the infoldings may be small, at other sites it is very large (Fig. 4). In addition, it is in direct contact with an important part of the nuclear surface and builds close connexions with deep-seated nuclear areas.

Palade[4] and others suggest that the mechanism of plasma membrane flow may play an important part in securing active transport of substances in both directions through the cytoplasm. Palade[4] has also shown that such cytoplasmic membranes are topographically often closely associated with mitochondria. Fig. 3 shows the nucleus of a cancer cell bounded by an undulating nuclear envelope: within the depressions mitochondria can be seen, closely associated with the nuclear membranes. Fig. 4 illustrates several deep indentations; at the opening of one of them lies a very large mitochondrion.

These nuclear membrane invaginations in cells with active protein synthesis suggest the existence of a mechanism of nuclear membrane flow compensating for increased metabolic exchanges between nucleus and cytoplasm.

Phosphatidyl Serine and Blood Coagulation

An important aspect of blood coagulation research is the chemical definition of the reacting substances and a question of current interest is the composition of platelet thromboplastic factor.

Previous reports[1,2] have described the clotting activity of brain lipid fractions containing phosphatidyl serine and phosphatidyl ethanolamine; the former inhibited thromboplastin formation while the latter showed acceleratory activity like that of platelet suspensions. Coagulation inhibitory activity has been ascribed to phosphatidyl serine extracted from brain[3,4]. However, Troup and Reed[5] have reported that both phosphatidyl serine and phosphatidyl ethanolamine isolated from platelets potentiated thromboplastin formation, the former compound being the more active. Biggs and Bidwell[6] were unable to associate platelet-like activity of brain phospholipids with any one substance; all were found to be acceleratory. Rapport[7] stated that a brain phosphatidyl serine preparation accelerated coagulation and that this was enhanced by lecithin. Rouser, White and Schloredt[8] found that acceleratory activity was confined to the phosphatidyl ethanolamine component of the platelet lipids.

We have now found that phosphatidyl serine can act as an accelerator (like platelets) or as an inhibitor (as previously reported) of thromboplastin formation, depending on the experimental conditions. Thromboplastin formation was inhibited when the phosphatidyl serine in aqueous solution was placed in the reaction mixture. However, when the phosphatidyl serine was first suspended in aluminium hydroxide adsorbed ethylenediamine tetraacetic acid plasma and then added to the reaction mixture, thromboplastin formation was enhanced. This potentiating effect was not found when citrated or oxalated plasma was employed.

Table 1. Thromboplastin Formation as affected by variously prepared Materials with and without Phosphatidyl Serine
The figures in the body of the table express clotting time of the substrate in seconds

	Test material	Incubation time (min.) 2	4	6	8	10
	Buffered saline	60	43	30	26	25
	Platelets	26	10	9	9	10
P.S. 2 mgm./ml. in	EDTA plasma	75	14·5	10·5	10	10
	Citrated plasma	96	66	55	54	50
	Oxalated plasma	100	75	57	52	46
	0·005*M* EDTA	112	103	89	89	85
	Buffered saline	116	105	100	80	77
	EDTA plasma	90	56	43	34	33
	Citrated plasma	82	44	27	23	26
	Oxalated plasma	81	45	37	35	30
	0·005*M* EDTA	92	64	48	42	36

P.S., phosphatidyl serine; EDTA, ethylenediamine tetraacetic acid.

The phosphatidyl serine was prepared from pork brain and on paper chromatography (method of Marinetti and Stotz[9]) consisted of phosphatidyl serine with traces of the lyso compound. Thromboplastin formation was measured by the Biggs–Douglas test[10]. Plasma poor in platelets was separated from normal human blood collected into 1/10 volume of each of the following anticoagulants: 0·027 *M* ethylenediamine tetraacetic acid (the disodium salt of ethylenediamine tetraacetic acid), 0·1 *M* sodium oxalate, and 0·13 *M* trisodium citrate. These plasma were then treated with aluminium hydroxide to remove prothrombin and related factors. The one-stage prothrombin time (with brain thromboplastin) of the adsorbed ethylenediamine tetraacetic acid plasma was greater than 10 min. The phosphatidyl serine was suspended in each of the three plasmas, in buffered saline, and in 0·005 *M* ethylenediamine tetraacetic acid, to a concentration of 2 mgm./ml. Each suspension (0·2 ml.) was substituted for platelets in the Biggs–Douglas test.

The results are shown in Table 1. The buffered saline suspension of phosphatidyl serine was clearly inhibitory. (As previously reported[2], inhibition was also found in the presence of platelets.) However, the phosphatidyl serine in ethylenediamine tetraacetic acid plasma simulated the acceleratory activity of platelets; this activity was maximal at 0·5 mgm./ml. On the other hand, the phosphatidyl serine in oxalated or citrated plasma was somewhat inhibitory or inert. To investigate the activating effect of ethylenediamine tetraacetic acid plasma, the possibility that this acid alone produced the change was examined. The phosphatidyl serine in 0·005 *M* ethylenediamine tetraacetic acid (the calculated plasma concentration) showed only inhibitory activity.

The possibility of some interaction with other lipids[7] in the presence of ethylenediamine tetraacetic acid was also investigated. The total lipids from platelet-poor plasma was mixed in varying proportions with the phosphatidyl serine in 0·005 *M* ethylenediamine tetraacetic acid. Under these conditions only inhibitory activity was found. This result does not exclude the possibility of lipid interactions under other conditions.

Our phosphatidyl serine preparation (in buffered saline) at appropriate concentrations also accelerated the coagulation of citrated plasma by Russell viper venom ('Stypven' of Burroughs Wellcome) although at higher concentrations venom activity was depressed.

We have detected both phosphatidyl serine and phosphatidyl ethanolamine (as well as other lipids) in normal human platelets by paper chromatography. This finding is in agreement with that of Troup and Reed.

These observations may help to resolve some of the apparently conflicting reports referred to earlier. They also show that the activity of a substance (at constant concentration) may be reversed, thus emphasizing the importance of the particular assay conditions. This work will be reported in greater detail elsewhere.

Standard Atmospheres in Respiratory Physiology

Pugh[1], observing on Everest pressures "higher than those calculated according to the standard altimeter calibration" with differences physiologically important above 18,000 ft., rejects the International Commission for Air Navigation (ICAN) 'atmosphere', preferring the temporarily more convenient formula of Zuntz *et al.*[2]. This formula promises to achieve a mystical superiority in high-altitude physiology[3].

The International Commission for Air Navigation 'atmosphere', an approximate world mean atmosphere convenient for altimeter calibrations, is, like any other calculated from simplified formulæ, inaccurate when surface pressure or vertical temperature distribution differs from 'standard'. To correct an altimeter reading accurately, whatever model atmosphere its basis, the complete vertical distribution of virtual temperature below the observer must be known. Assumed 'mean temperatures' will only by chance be satisfactory, particularly if temperature inversions exist below.

Haldane and Priestley[4] and Miss Fitzgerald[5] did not "indicate that the (Zuntz) formula is a better guide to barometric pressure in mountains than the accepted formula for calibrating altimeters" (Pugh, ref. 1). They were clear that the success of any simple formula which does less than fully integrate the weight of air below the observer depends on locality and season. It is unfortunate, therefore, to imply that the Zuntz formula somehow fits "conditions in mountains rather than free air", taking no account of time and place. On a similar mountain in high latitudes, actual pressures would have been lower than those of the International Commission for Air Navigation atmosphere.

Fig. 1 shows the mean departures from the International Commission's 'atmosphere' of the actual seasonal mean pressures measured at three representative latitudes along meridian 80° W. (from data published in a different form[6]). These curves are idealized. Secular variation, continental, oceanic and local topographical climatic influences scatter individual observations considerably, but the pattern is clear: at low latitudes, mean pressures exceed those of the International Commission 'atmosphere', increasing with height to about 10 per cent excess at 40,000 ft., whereas at high latitudes in winter the situation is reversed.

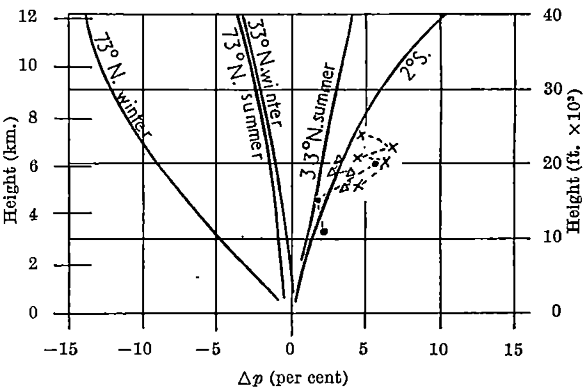

Fig. 1. Seasonal mean pressure deviations from the International Commission for Air Navigation pressures as a function of height, latitude and season. Δp, Excess pressure at each height as a percentage of the International Commission pressure; ●, Pugh (1952) Cho Oyu; △, Williams (1956) Karakoram; ×, Pugh (1953) Everest

Hess's values are fairly representative; the range in height of the mean January and July 300 mb. pressure-levels computed by Bannon[7] confirm these results, as do those of Wexler[8].

Given the local air temperature, differences between the International Commission's heights and those in the real atmosphere at which a given pressure is reached may be computed. Thus, in low latitudes, the International Commission's pressure for 40,000 ft. is usually attained at 42,000 ft. and at high latitudes in winter it is already reached at 37,000 ft.

Since even 'standard' atmospheres display secular drift[8], it may be preferable in high-altitude physiology to think first in terms of pressure, preferably directly measured, relegating altitude *per se* into its evident secondary role.

A final comment may avoid confusion. Pugh, discussing pulmonary ventilation, states that "normal variability of resting ventilation . . . is such that one would not expect to see any close relationship with relatively small changes in altitude, particularly at higher altitudes where change of barometric pressure with height is considerably less than at sea level". This poor correlation is probably entirely due to biological variability. At these altitudes, the fractional pressure change with height, which is the relevant factor, is in fact more rapid than lower down.

The Enigmatical Trematode "*Dictyocotyle coeliaca*"

Dictyocotyle coeliaca Nybelin, 1941, the only monogenetic trematode ever to be found in the cœlom of a vertebrate, was described from two specimens, one from *Raia lintea* near Skagen and the other from *R. radiata* at Trondheim. Ten years ago one of us described two other specimens from *R. clavata* and expressed the hope that a look-out would be kept for the trematode in zoological laboratories[1]. This appeal brought nine specimens from J. E. N. Sloan, formerly of the Zoology Department, University of Edinburgh, and it seems to have led to the publication of two original papers. In neither paper was the total number of parasites specified, but 16 out of 55 *Raia naevus* and 31 out of 73 *R. radiata* taken on Scottish fishing grounds[2] and 35 out of 135 *R. naevus* landed at Plymouth[3] were infected. Mean numbers of parasites per fish were 7 and 4 respectively, and in each instance rays of other species did not yield any parasites. This trematode closely resembles the common cloacal parasite *Calicotyle kroyeri*, differing chiefly in the nature of the posterior adhesive organ (opisthaptor), which is a delicate hookless disk showing faint markings or irregular shapes and sizes. These simulate but are not suctorial compartments, or loculi, such as are found in *Calicotyle* and other Monocotylidae, and mainly for this reason the taxonomic status of *Dictyocotyle* remains undetermined. Llewellyn and Green[3] believe it "distinctly possible" that the host landed at Brixham "had been mis-identified". When at the time confirmation was sought, Dr. E. B. Francis was emphatic, stating, "the species of *Raia* (as mentioned in my previous letter !) was '*clavata*', source Brixham" (letter dated March 26, 1947).

With the finding of new specimens, the senior author recognized the possible validity of the species, though not of the genus[1]. This brought from Dr. H. A. Baylis the comment (*in litt.*, May 3, 1948) : "I cannot help feeling sorry that you have now given your blessing to what I am quite sure is a fictitious species. In your book 'The Trematoda' you said, 'in any case it seems safe to assume . . . that *Dictyocotyle coeliaca* is an abnormal form of a species of *Calicotyle*, probably *C. kroyeri*'. With that view I entirely agree, and still agree, having seen the specimens found at Cambridge, to which you refer". However, the authors of the two papers mentioned[2,3] have accepted both genus and species as valid. Such a taxonomic tangle would be a small matter were it not for the extraordinary nature of the trematode concerned. This and the appeal for new specimens has induced the junior author to examine over a period of five years *Raia radiata* obtained from Plymouth, with the result that 38 additional specimens have been found. Of these, 27 were taken from the anterior part of the liver, 3 from the vicinity of the kidneys, and 7 from the body cavity quite near the openings of the abdominal canals. The canals themselves were dissected consistently and one trematode was actually found inside one of them. Evidently, it had been preserved in the act of passing from the cloaca into the body cavity, and the longitudinally folded condition of the body indicated that passage had not been easy. Moreover, this specimen had lost the opisthaptor, the stalk and adjacent tissue remaining as a kind of button or boss. The missing haptor was not found in this instance, but six isolated opisthaptors were recovered from the cloaca in other instances, along with a total of 317 entire specimens of *Calicotyle kroyeri*. These adhesive organs had evidently been torn from the body of the trematode, each of them having a central perforation which matches the boss of the mutilated specimen (Fig. 1*B*). The boss thus seems to correspond to the stalk plus the torn-out central portion of the opisthaptor (cf. Fig. 1*A*). It was observed also that such mutilation can be induced artificially, presumably because of a line of weakness between the central and peripheral portions of the opisthaptor.

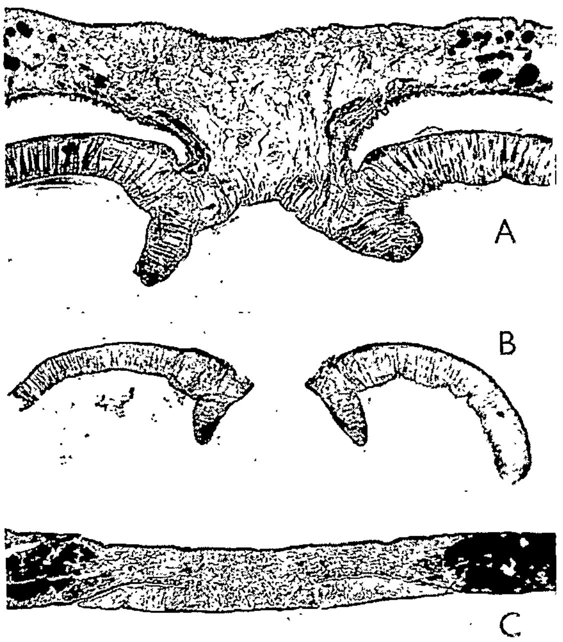

Fig. 1. Transverse sections, dorsal side above, ventral side below. (*A*) *Calicotyle*, showing part of the body (above) and two loculi of the haptorial disk plus the central boss (below). (*B*) discarded opisthaptor of *Calicotyle*, two of the peripheral loculi indicated, boss missing. (*C*) '*Dictyocotyle*', showing the delicate disk without loculi (below) which, it is suggested, is regenerated from the boss of a mutilated specimen

Because of these findings we give it as our considered opinion that *Dictyocotyle coeliaca* is simply a cœlomic form of *Calicotyle* which has entered the body cavity via one of the abdominal pores, which has lost the normal opisthaptor, and which has afterwards modified the central boss by regeneration in such a manner as to produce a delicate hookless disk without true loculi, that is, a pseudohaptor. This conclusion is supported by histological findings regarding the structure of the opisthaptor in the cœlomic form, which shows none of the characters of the normal adhesive organ of the Monocotylidae and which, like the boss of the mutilated form, shows a paucity of muscular tissue (Fig. 1*C*).

That *Calicotyle* may penetrate the slit-like abdominal pores of certain rays is certain, and in one instance on record the trematode did not lose its opisthaptor. This specimen was collected on April 7, 1868, by L. Esmark in the body cavity of *R. radiata.* Apropos of this record Brinkmann has stated[4]; "this location must be assumed to be accidental, or more probably erroneous. The location might suggest the parasite to be *Dictyocotyle coeliaca* Nybelin, but the examination of this specimen, however, shows that it is undoubtedly *Calicotyle kroyeri*". There is no reason, we believe, to doubt the record of Esmark, who discovered at least three trematodes new to the Norwegian fauna. If *Calicotyle* penetrates the cœlom without mutilation identification is easy; what is not easy is to recognize the after-effects of mutilation, or of existence in a wrong location. Regeneration seems to modify the boss of the mutilated trematode in various ways, leading to the inconstant patterns of markings on the disk ultimately formed (cf. the figures in refs. 1; 2, Fig. 1 (5); and 3, Pl. 1, Fig. 1).

We believe that Baylis was not very wide of the mark when he wrote regarding the damaged haptor (*loc. cit.*): "When torn away from the cloaca, the worm sometimes leaves behind the ventral half of its opisthaptor, still no doubt firmly attached. The dorsal half of this organ shows a reticular pattern due to the presence of a complicated system of muscle fibres which radiate like rosettes from a number of centres, and it is this reticulation which produces the appearance of a large number of loculi, as I have demonstrated by re-staining the Cambridge specimens". (These specimens, we might add, are the ones which Brinkmann identified as *Dictyocotyle coeliaca*, not in 1952 as Llewellyn and Green indicated, but in 1943, that is about five years before Baylis re-examined them.) We doubt the loss of the ventral half of the haptor, however, and suggest that it is the regenerating boss of the mutilated haptor which develops a reticular pattern, for such a reason as Baylis gave. The problem requires further investigation and is being investigated. We would suggest to others interested in the problem that what is required is information on the incidence of both cloacal *and* cœlomic forms where these co-exist, and particularly of the factors which influence the transition. It would be useful also to study the reasons for the failure of the cloacal forms to penetrate into the body cavity of certain species of *Raia* which harbour species of *Calicotyle*.

Tubule Formation in Rat Brains by Monkey Kidney Cells previously grown *in vitro*

THE brain has been employed in this laboratory as a site for the transplantation of malignant cells from tissue culture to rat[1], and such transplantations are proving useful for both oncological and virological investigations. On the assumption that this procedure may also provide a new approach for the study of the nature and mechanism of alterations occurring in cells grown *in vitro* it was decided to apply the procedure to normal monkey cells grown in tissue culture.

Primary cultures of *M. rhesus* kidney were harvested from bottles by means of trypsin (0·06 per cent), centrifuged at 100*g* and resuspended in an amount of diluting material so as to yield approximately 15 million cells per ml. The diluting materials were either the growth medium used for *in vitro* cultivation of cells (solution 199 plus 5 per cent calf serum) or the supernatant fluid from a crude extract of tumour tissue (usually rat-passaged tumour derived from Hep 3 carcinoma). The suspended cells were injected intracerebrally (0·1 ml.) into young Wistar rats which had previously received X-radiation (320 r.) and cortisone (two injections of 3–5 mgm. each). At several intervals the animals were killed and the brain removed for histological examination. The results showed that not only did monkey renal cells survive and perhaps multiply in the rat brain, but also that these cells actually assembled in groups giving rise to tubular structure. One could find epithelial-like cells in nests, aggregates and tubular arrangements in various parts of the brain. The tubular structures were especially prominent, in several instances, in the meninges of the sulci. This is shown in Fig. 1. At first it was thought that tubule formation was more pronounced following the exposure of the cells to tumour extract. Subsequent experiments did not reveal such an 'inducing' capacity in the extracts.

Thus, cells derived from adult kidneys, dissociated from their original organization, cultivated in an undifferentiated monolayer *in vitro* appeared com-

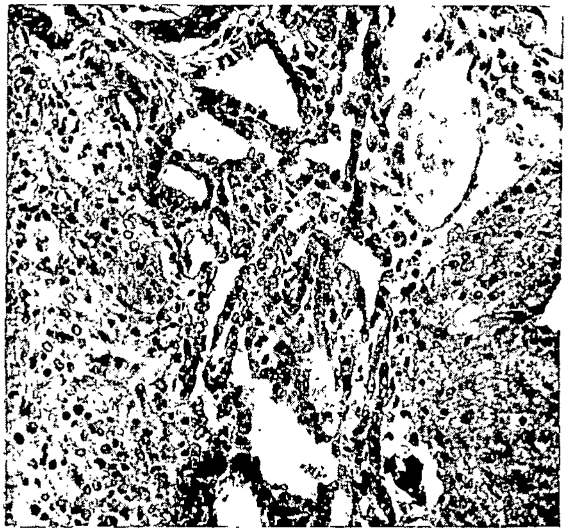

Fig. 1. Brain seven days following injection of trypsinized monkey kidney cells in tissue culture. There are numerous epithelial tubules in the meninges of a cerebral sulcus. Hæmatoxylin and eosin stain. (× 160)

petent to reconstruct the structure of their origin. Is this ability resident in adult kidney epithelium ? According to Oliver *et al.*[2], nephron reconstitution as contrasted with epithelial cell regeneration in damaged kidney requires the presence of an intact basement membrane. An experiment testing this point has not yet been done. It remains to be determined whether the sojourn of the cells in tissue culture plays a part in evoking this phenomenon. The relationship of the phenomenon to kidney tubule formation from dissociated chick embryo nephroblasts[3] *in vitro* or to the development of tubules and glomeruli in rat brain implanted with metanephrogenic rudiments and metanephrogenic mesenchyme recently reported by Grobstein and Parker[4] is as yet not known. Nor is it known from the work done thus far whether the brain plays a part as an organizer or inducer in tubule formation. Be it as it may, the present findings attest further to the utility of the brain as a transplantation site—a fact well documented by workers[5-8] using malignant or embryonic tissues.

We are grateful to Dr. Albert M. McCallen, chief radiologist, and to Mr. Mack Holcomb, therapy technician, of the Veterans Administration Hospital at Coral Gables, for providing equipment and assistance for irradiation of the animals.

Adaptive Muscular 'Allomorphism'

A new method for quantitatively extracting the sarcoplasm and myofibril proteins from striated skeletal muscle and enabling them to be estimated separately has been described in a recent publication[1]. With the aid of this method, it has been shown (as summarized in Table 1) that various types of atrophy modify more or less drastically the protein composition of the calf muscles in rabbits.

Table 1

Treatment	No. of rabbits	Weight loss (per cent)	Total nitrogen content (mgm./gm. muscle tissue)	Nitrogen components as percentage of total nitrogen			
				Myofibril	Sarcoplasm	Stroma	Non-protein
Controls	50	—	32·3±0·2	57±0·6	25±0·5	8±0·1	10±0·1
Denervation	16	33·1	26·0±0·6	50±0·8	24±0·6	16±0·5	11±0·3
Tenotomy	16	32·5	26·4±0·5	53±1·8	26±1·4	12±0·5	11±0·3
Plaster cast	16	21·0	30·4±0·5	48±1·2	29±0·8	11±0·5	12±0·2

As shown by Table 1, after tenotomy and neurotomy the amounts of total nitrogen, sarcoplasm and myofibril proteins are smaller, but the percentage of stroma proteins is greater than is normally the case. After disuse-atrophy induced with a plaster cast, the total nitrogen content diminished less than after tenotomy or neurotomy, the percentage of myofibril proteins declined and the proportion of sarcoplasm proteins rose. Accordingly, disuse-atrophy reduces selectively the contractile myofibril proteins, an observation I am inclined to interpret as a sign of adaptation to altered working conditions.

I have now completed another series of experiments on rabbits the movements of which were restricted by confinement in a small space. Three groups of adult white rabbits of similar initial age and weight were used as follows. (1) 10 rabbits served as controls and their activity was in no way restricted ; (2) 5 rabbits were kept for 6 months in cages having a floor area of 35 cm. × 70 cm. and a height of 35 cm. ; (3) 4 rabbits were kept for 3 years in cages of the same type as group 2.

All the rabbits seemed healthy throughout and, except as described above, were exposed to identical experimental conditions. While the contribution of age changes to the effects of restricted activity might have been appreciable in group 3, this is unlikely to be so in group 2.

The total nitrogen and the percentages of protein- and non-protein-nitrogen in the thigh muscles were estimated for each animal as described previously[1]. The results are shown in Table 2.

Table 2

Animal no.	Mgm. total nitrogen per gm. muscle tissue	Nitrogen components as percentage of total nitrogen content			
		Myofibril	Sarcoplasm	Stroma	Non-protein
Group 1					
1	32·8	59	26	5	10
2	32·1	58	25	7	10
3	34·0	60	24	6	10
4	32·6	62	23	6	10
5	31·8	57	27	7	10
6	33·1	56	27	6	11
7	32·9	61	23	6	10
8	32·4	60	24	6	11
9	32·7	59	24	6	11
10	33·4	62	22	7	9
Mean	32·8	59	25	6	10
Group 2					
11	33·4	52	31	6	11
12	32·9	52	33	4	10
13	34·1	51	33	6	10
14	32·0	49	34	6	11
15	32·8	53	31	7	10
Mean	33·0	51	32	6	10
Group 3					
16	34·3	40	44	6	11
17	35·2	39	44	6	11
18	32·6	44	41	5	10
19	34·2	41	43	6	10
Mean	34·1	41	43	6	10

This shows that the amount of total nitrogen and proportions of stroma- and non-protein-nitrogen remained practically unchanged. In group 3, moreover, the percentage of myofibril nitrogen—which in the controls was more than twice as high as that of sarcoplasm nitrogen—had declined by about one-third, and the percentage of sarcoplasm nitrogen had increased to about the same level as myofibril nitrogen. Changes with the same tendency were observed in group 2.

Since atrophy invariably increases the proportion of stroma in a muscle, and since it remained unchanged here, this shift cannot have been caused by any kind of atrophy. Nor can pathological factors have been involved. But the muscles in group 2, where age changes cannot have occurred, exhibited changes of apparently the same fundamental type as, only of lesser degree than, the changes observed in group 3. However, the possibility that ageing might produce similar changes in animals that have maintained a constant activity-level throughout their lives cannot be ruled out entirely. Yet irrespective of how the variation arises, the composition of the muscle cell can evidently vary greatly from one normal individual to another.

Changes of this type—for which allomorphosis would seem to be an apt term (ἄλλοσ, other; μορφή, shape)—are due to adaptation of the cell in various circumstances, the degree of activity being a causative factor in the case of the muscle cell. Conceivably, other cells in the organism also undergo allomorphosis.

Hitherto the consensus of opinion appears to have been that the cells in a tissue are of fairly constant composition, and that the proportions of the various cell constituents will change greatly only under pathological conditions. But here it has been demonstrated that, at least in muscular tissue, the composition of individual cells may undergo considerable variations even under normal conditions.

Allomorphosis of the muscle cell must clearly be accompanied by changes in its contractile power. A muscle in which the cells contain a sharply reduced proportion of contractile proteins, and concomitantly an increased proportion of sarcoplasm proteins, cannot be as powerful as an unchanged muscle. Accordingly, because the composition of muscle fibres may vary so greatly, the contractile powers of two muscles cannot be compared solely on the basis of the effective areas of the muscle cross-sections.

Salt Requirements in the Tropics during Summer

IN a recent communication, Dahl[1] has stated that a considerable reduction in quantity of salt intake can be made from the existing levels, without any harm to the body. This may, on the other hand, be of great benefit in reducing the incidence of hypertensive cardiovascular disease. The treatment of hypertension by low salt diet is quite well established, but it was not known before that persons on habitually high salt diet are more prone to essential hypertension and its complications. Dahl has predicted that where salt diet exceeds 5 gm. of sodium per day (that is, 12·5 gm. sodium chloride) incidence of hypertension and its complications will be frequent.

This statement may be true of cold and temperate climates where there is practically no loss of salt in sweat and all the dietary salt is excreted in urine (negligible amounts also in fæces and saliva). In the tropics, on the other hand, excretion of salt in sweat is quite appreciable and is higher in those unacclimatized than in those acclimatized. This is because in acclimatized persons the concentration of salt in sweat is comparatively less, due to the influence of adrenal hormones. Therefore requirement of salt is different for the two. When, after living in a hot climate, a person gets acclimatized to heat, his requirement of salt is also reduced.

Our studies have shown[2] that in an environmental temperature of about 101° F. and relative humidity 54 per cent, acclimatized subjects sweating 3–5 l./day could be kept in salt balance on 6·2 gm./day. The requirement of salt has been found to increase proportionally with rise in dry-bulb temperature of the environment. When the maximum day temperature is about 110° F., the requirement of salt has been found to be about 15 gm. for an acclimatized person working for 8 hr. a day. These results have been supported by observations on ratings working in Indian Navy ships for 8 hr. a day in the engine room, where the dry-bulb temperature of the environments was of the order of 110° F.[3], and no case of salt deficiency was recorded on salt intake of 15 gm. a day. Observations in the textile industry in India[4] have also shown that there is no salt depletion in workers working at temperatures up to 86° F. effective temperature for 8 hr. on a normal salt intake of about 15 gm./day.

It has been also found[2] that the physiological requirement of salt is less than that needed for balancing taste in food. If enough salt is taken to satisfy the palate, there is very little likelihood of salt deficiency occurring in the body.

Low incidence of hypertension in India is not due to low salt intake as suggested by Dahl[1]; but is probably due to heavy losses of salt in sweat. The salt content of the Indian dietary varies from 14 to 24 gm. a day from north to south[5], which is more than that of Western countries, where the diet contains 10–15 gm. salt a day[6].

From the foregoing it can be concluded that about 15 gm. of salt (6 gm. sodium) is quite adequate for acclimatized persons engaged in manual work in the tropics, and that for sedentary persons about 6 gm. salt a day is quite enough.

My thanks are due to Prof. D. S. Kothari, scientific adviser to the Minister of Defence, for his interest in this work and permission to publish this communication.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, October 13

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Rationalization of the Avenues of Higher Education for Electrical Engineers".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"They Were Kafirs" (Colour films with commentary by H.R.H. Prince Peter of Greece).

Royal Institute of Chemistry, London Section (joint meeting with the Ewell County Technical College Faraday Society, at the Ewell County Technical College, Reigate Road, Ewell, Surrey), at 7 p.m.—Dr. T. W. Farthing: "The Chemistry and Applications of Beryllium".

Monday, October 13—Tuesday, October 14

Society of Chemical Industry, Food Group (at the Royal Society of Medicine, 1 Wimpole Street, London, W.1), at 9 a.m. on Monday and 9.30 a.m. on Tuesday—Symposium on "Texture in Foods".

Tuesday, October 14

Society of Chemical Industry, Agriculture Group (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Plant Constituents Meeting.

Institution of British Agricultural Engineers (at 6 Buckingham Gate, London, S.W.1), at 2.15 p.m.—Mr. A. E. H. Higgins: "Pest Spraying".

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

University of London (at Bedford College, Regent's Park, London, N.W.1), at 5.15 p.m.—Mr. D. L. Pratt: "The Antarctic Expedition" (Stevenson Lecture).*

Society of Chemical Industry, Chemical Engineering Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. K. W. J. Bowen: "Titanium and its Alloys as Materials of Construction for Chemical Plant".

Plastics Institute, London and District Section (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—"Thermoplastic Pipes" (Open Forum).

Wednesday, October 15

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. D. J. Bell: "Carbohydrate Metabolism".*

Institute of Navigation (at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting. Captain F. J. Wylie, R.N.: "Automation in Marine Navigation" (Presidential Address).

Royal Meteorological Society (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Mr. W. G. Harper and Mr. J. G. D. Beimers: "The Movement of Precipitation Belts as Observed by Radar"; Mr. N. P. Sellick: "Modification of the Structure of a Tropical Cyclone on Traversing a High Plateau".

British Coal Utilization Research Association (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 5.30 p.m.—Sir Charles Goodeve, F.R.S.: "Carbon—The Key to Metallurgy" (Seventh Coal Science Lecture).

Eugenics Society (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. Christopher Tietze: "Human Fertility—Statistical Considerations".*

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.30 p.m.—Mr. J. F. Outram: "Electrical Power Generation and Its Future in Southern England" (Chairman's Address).

Society for Analytical Chemistry, Microchemistry Group (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion on "The Role of the Microchemist in Industry" opened by Mr. C. Whalley and Mr. G. Ingram.

Royal Institute of Chemistry, London Section (at King's College, Strand, London, W.C.2), at 7 p.m.—Prof. R. L. Wain: "Systemic Fungicides".

Thursday, October 16

Royal Anthropological Institute of Great Britain and Ireland (at 21 Bedford Square, London, W.C.1), at 5.30 p.m.—Dr. Herman Lehmann: "Abnormal Hæmoglobins".

University of London (at the Beveridge Hall, Senate House, London, W.C.1), at 5.30 p.m.—Sir Edward Salisbury, F.R.S.: "The Influence of Botany on Health and Disease".* (First of eleven lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation. Further lectures on October 21, 23, 28, 30, November 18, 20, 25, 27, December 2 and 4.)

Society of Chemical Industry, Road and Building Materials Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Mr. D. H. Mathews: "Surface Active Agents and Surface Dressing".

Chemical Society (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, South Kensington, London, S.W.7), at 7.30 p.m.—Dr. G. Herzberg, F.R.S.: "Spectra of Free Radicals" (Centenary Lecture).

Royal Aeronautical Society, Graduates' and Students' Section (at 4 Hamilton Place, London, W.1), at 7.30 p.m.—Major P. L. Teed: "The Fatigue of Aircraft".

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Sir Philip Manson-Bahr, C.M.G., D.S.O.: "The March of Tropical Medicine during the Last Fifty Years" (First Manson Oration).

Thursday, October 16—Friday, October 17

British Interplanetary Society (in co-operation with the Royal Air Force Institute of Aviation Medicine, at the Great Hall, B.M.A. House, Tavistock Square, London, W.C.1), at 9.30 a.m. daily—Space Medicine Symposium.

Friday, October 17

Institute of Rural Life at Home and Overseas (at Friends' International Centre, 32 Tavistock Square, London, W.C.1), at 1.15 p.m.—The Rt. Hon. the Earl de la Warr, G.B.E.: "Developments in Central Africa".*

British Institute of Radiology incorporated with the Röntgen Society (in the Reid-Knox Hall, 32 Welbeck Street, London, W.1), at 2 p.m.—Radiobiology Meeting.

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Air Marshall Sir Owen Jones, K.B.E.: "The Mechanical Engineering of Aircraft Mechanisms" (Presidential Address).

Saturday, October 18

Biochemical Society (in the Chemistry Lecture Theatre, Royal College of Science, London, S.W.7), at 2 p.m.—376th Meeting.

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Dr. K. P. Wachsmann: "African Musicians—a Close-up View of Folk-Music in Uganda".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Organic Chemistry; and an Assistant, Grade "B" (with special interests in botany) in Biology at Birkenhead Technical College—The Director of Education, Birkenhead Education Committee, 63 Hamilton Square, Birkenhead (October 15).

Assistant Lecturer (Grade B) in Telecommunications and Electronics—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18 (October 17).

Principal Scientific Officer (with a degree, preferably with honours, in horticulture or related science, and experience of horticultural crops, particularly those grown under glass) as Head of a new Horticultural Research Department—The Secretary, Glasshouse Crops Research Institute, Worthing Road, Rustington, Littlehampton, Sussex (October 20).

Research Physicist (preferably with experience in the use of ultra-high vacuum systems or in the chemical physics of surfaces) in the Department of Physics, for which work will involve electrical measurement applied to the study of surface contamination processes on semiconductors—The Professor of Physics, University of Reading, Physics Research Laboratories, Upper Redlands Road, Reading, Berks. (October 24).

Temporary Assistant Lecturer or Temporary Lecturer (preferably with interests in applied mathematics) in the Department of Mathematics—The Secretary, University College, Gower Street, London, W.C.1 (October 27).

Assistant Lecturer (graduate in chemistry, agricultural chemistry, biochemistry or some similar subject) in the Department of Physiological Chemistry, to deal specifically with dairy chemistry and related biochemical topics—The Registrar, Room 29 (O.R.B.), The University, Reading (October 31).

Assistant Lecturer (with a suitable first degree with a qualification in statistics, and interested in the application of statistical techniques to biological or social sciences) in Statistical Theory and Experimental Method—The Registrar, Wye College (University of London), near Ashford, Kent (October 31).

Lecturer in Agricultural Chemistry (Biochemistry); a Lecturer in Agricultural Chemistry (Soil Science) in the Department of Agricultural Chemistry, Waite Agricultural Research Institute; and Lecturers (2) in Plant Breeding and Genetics in the Department of Agronomy, Waite Agricultural Research Institute, University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer in Psychology at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, October 31).

Lecturer or Assistant Lecturer in Cytology in the Department of Genetics—The Registrar, The University, Birmingham 15 (October 31).

Professor of Inorganic and Analytical Chemistry at the University of Natal, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, October 31).

Research Assistant (with a first- or second-class honours degree or a research degree in chemistry and an interest in biochemistry), to participate in chemical investigations of fluorine-containing carbohydrates—Dr. P. W. Kent, Department of Biochemistry, South Parks Road, Oxford (October 31).

Scientific Officer (with a good honours degree in botany, genetics or agricultural botany, and preferably postgraduate training in genetics) in the Department of Plant Breeding, to study the genetics and breeding of the tomato with particular reference to disease resistance—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford (October 31).

PHYSICIST (with at least a university honours degree in physics with a minimum of two years research experience) IN THE DIVISION OF PLANT INDUSTRY, Commonwealth Scientific and Industrial Research Organization, Canberra, A.C.T., Australia, to join a research team working on the moisture and energy balance of natural surfaces—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 130/329 (November 1).

JUNIOR LECTURER IN PHYSIOLOGY—The Registrar, Trinity College, Dublin (November 3).

SENIOR LECTURER IN ANATOMY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 7).

REGIUS CHAIR OF BOTANY in the University of Aberdeen—The Private Secretary, Secretary of State for Scotland, St. Andrew's House, Edinburgh 1 (November 10).

LECTURER (preferably with special qualifications in algebra) IN PURE MATHEMATICS—Prof. H. Jones, F.R.S., Mathematics Department, Imperial College of Science and Technology, London, S.W.7 (November 15).

RESEARCH STUDENTS AND RESEARCH FELLOWS IN THE SCHOOL OF PHYSICS, University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 15).

LECTURER IN INORGANIC AND PHYSICAL CHEMISTRY at the University of New England, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 30).

BROTHERTON CHAIR OF CHEMICAL ENGINEERING in the Houldsworth School of Applied Science—The Registrar, The University, Leeds 2 (January 31).

ASSISTANT LECTURER, Grade B (honours graduate in physics and preferably with teaching and/or industrial experience) TO TEACH PHYSICS up to General Certificate of Education, Advanced Level, and National Certificate standard—The Principal, Enfield Technical College, Queensway, Enfield, Middlesex.

CHEMIST (with a good honours degree in inorganic chemistry or equivalent) IN THE GEOLOGICAL SURVEY DEPARTMENT, Government of Tanganyika, for the analysis of rocks, minerals and ores, and the supervision of junior staff in routine analytical work—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD. 105/8/09/T.

COMPUTER (with pure and applied mathematics to G.C.E. advanced level) IN THE PHYSICS DEPARTMENT, for work on rocket and satellite research in the upper atmosphere—The Secretary, University College, Gower Street, London, W.C.1.

LECTURER IN THE PHYSICS DEPARTMENT, Sunderland Technical College, to teach some branch of applied physics to Higher National Certificate or Diploma in Technology level—The Director of Education, Education Offices, 15 John Street, Sunderland, Co. Durham.

LECTURER (preferably with an interest in geomorphology and/or geology) IN GEOGRAPHY in the Training Department—The Warden, Goldsmiths' College (University of London), New Cross, London, S.E.14.

RESEARCH ASSISTANT (graduate interested in electrochemistry), to work on a problem connected with the electro-deposition of metals from solutions containing complexing agents—The Head of the Department of Applied Chemistry, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

SCIENTIFIC OFFICERS (with a first- or second-class honours degree, preferably in physics or electrical engineering), to carry out original research in electronics on a wide variety of interesting problems which arise in nuclear physics and which cannot be solved by present available techniques and equipment—The Senior Recruitment Officer, The Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. 2021/34.

SENIOR LECTURER (with a specialized knowledge of microbiology with particular reference to industrial processes, and actively interested in research) IN THE DEPARTMENT OF BIOLOGICAL SCIENCES—The Registrar, Bradford Institute of Technology, Bradford 7.

SENIOR RESEARCH WORKER (with a Ph.D. degree or equivalent research experience) IN THE PHYSICS DEPARTMENT, for upper atmospheric research (using Skylark rockets)—The Secretary, University College, Gower Street, London, W.C.1.

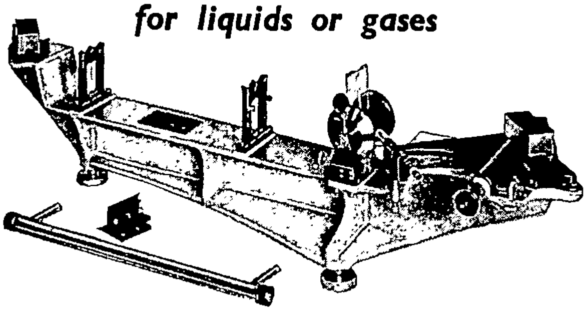
PRECISION BS INSTRUMENTS

Jamin Refractometer
for liquids or gases



Average accuracy in measurement of refractive index is approximately 0·000001 for gases and 0·000002 for liquids.

The elimination of all spring adjustment to the mirrors results in great stability and freedom from vibration. Worm wheel gearing actuates the compensator. Tubes up to 50 cm. length can be used.

EDUCATION: AN INVESTMENT FOR THE FUTURE

THE correspondence between Sir Philip Morris, chairman of the National Advisory Council on the Training and Supply of Teachers, and the Minister of Education, on the supply of teachers in Britain in the 1960's, was published* shortly after the statistics given in the Ministry's annual report for 1957 had indicated that, so far from the 'bulge' flattening out, a new peak was likely in 1968, and had again stressed the need for a considerably larger number of teachers of mathematics and science to deal with the increasing number of children in the secondary schools. In his letter, dated July 16, Sir Philip sets forth the Council's views on the situation since its fifth report, on three-year training for teachers, was published in September 1956, in the light of this probable increase in the number of children in the schools; and he gives a revised estimate of wastage of teachers, and the actual number of candidates offering themselves for training.

On wastage, the Council is inclined to attribute the sudden increase mainly to an increased loss of women teachers through earlier marriage and child-bearing, and it has now provisionally adopted the conservative assumption that the annual increase of teachers in Britain in the future will be either 6,000 or 5,000. To obtain the objective of reducing sizes of classes to a maximum of forty in the primary and thirty in the secondary schools by 1968 now appears likely to require 326,000 teachers instead of the 299,000 previously assumed, and on the higher estimate of wastage the number of teachers likely to be available is 282,000. The Council concludes that if the staffing objectives are to be attained, the short-fall of teachers in January 1968 is unlikely to be less than 34,000. The present position as regards the supply of candidates offering themselves for training is regarded as satisfactory and likely to remain so in 1960 and to an increasing extent in later years.

Nevertheless, the Council emphasizes the need for new decisions and urgent action to maintain the annual rate of increase in the total number of teachers available by 1968 at the higher level now seen to be required. Nothing less, it believes, than an annual output of 12,000 teachers from the three-year course will suffice to maintain the present annual output of about 10,000 teachers and make good over five years the loss of 10,000 teachers in the year of intermission. Accordingly, the Council recommends provision of 16,000 additional places to bring the capacity of the training colleges to 36,000 places; it is regarded as being of the utmost importance that these places should be available by the autumn of 1962. It is suggested that, with this expansion, the present pattern of teacher training should be re-examined. Particularly in planning new colleges and the expansion of existing colleges, attention should be given to the optimum size of a college for economic working, and the continuation on their present basis of the existing specialist colleges should be reconsidered. As regards location, colleges should be in, or readily accessible to, a university town or similar educational or cultural centre, and the general spread of colleges should take into account the existence of areas where the authorities have difficulty in recruiting enough teachers.

Even in this situation, however, the Council is not prepared to recommend postponement of the introduction of the three-year course from 1960 to 1961, and it believes that by taking urgent action on the lines suggested the position up to 1968 can be made reasonably satisfactory if a building programme of this size is put in hand in time. In acknowledging the letter, the Minister said that he was considering the Council's advice as a matter of urgency and on September 21 he announced that 12,000 new places would be provided in the training colleges to be completed by 1962 at a cost of about £15 million.

It is this note of urgency that is needed at all stages if the nation is to receive the full return from the increasing effort now being devoted to education. Notably is this true of technical education. Although a pamphlet recently issued by the Central Office of Information and the Ministry of Education fully supports what Sir Willis Jackson said at Glasgow as to the need for industry effectively to discharge its responsibilities to enable employer and employee, and through them the nation, to gain the full benefit, something more than the exhortation and guidance given in that pamphlet may be required to make industry, and particularly the small firms, take an adequate part.

It is not sufficiently realized yet that the bulk of technical training is given, and will continue to be given, in factories and offices. Most technical, much technological, and all apprenticeship training is in fact based on industry; the Ministry of Education and the local education authorities can only provide the framework of a system of technical education. Moreover, for every additional technologist, it is necessary to produce six additional supporting technicians or craftsmen—the latter mainly by the apprenticeship system—if there is not to be waste of highly skilled man-power.

It is from this point of view that grave doubts exist as to whether we are yet in sight of getting the full return from the Government's proposals, and whether by themselves they are adequate, particularly in view of the marked indifference of the smaller firms and the poor quality of the technical training they give. It is partly a question of economics, of the measures to be taken both to organize the supply of recruits and teachers, and equally to see that the most effective use is made of our existing institutions and man-power, and to ensure that the man-power once trained is not wasted. Much of the attention given to education at the recent British Association meeting at Glasgow might be regarded as concerned with these aspects: it underlies, for example, the discussions on education in a technological age, and was much in Prof. W. R. Niblett's mind in discussing the value, function and opportunities of residential halls in the modern university.

---

* The Supply of Teachers in the 1960's—Correspondence between the Chairman of the National Advisory Council on the Training and Supply of Teachers and the Minister of Education, July, 1958. Pp. 12. (London: H.M. Stationery Office, 1958.) 9*d*. net.

In the former discussion, Prof. F. A. Vick's plea for greater flexibility in courses has a firm economic basis, as tending to reduce the risk of expensive failures. Experience at the University College of North Staffordshire, he pointed out, shows the value of experiment and the possibilities of doing more to break down the barriers between the arts and the science sides and to encourage the wider outlook which industry, for example, increasingly demands of its entrants. It is interesting to recall in this connexion that in a recent broadcast talk in which he discussed the teaching of undergraduates in the humanities, Prof. P. H. Nowell-Smith, professor of philosophy in the University of Leicester, insisted that some study of science should be compulsory for all such students. For good or ill, our lives, both public and private, are, in fact, very much influenced by scientists, and if intelligent decisions are to be made, those making them must have some understanding of what science is.

That, in other words, is a plea for more effective teaching on the grounds of efficiency, and nothing less underlies the present developments and experiments in halls of residence. Prof. Niblett is convinced that this activity is worth while from its contribution to the quality and character of the graduates; but it can still be open to experiment as to how best the educational contribution of a good hall of residence can be made, and whether we have yet found the best economic answer from the point of view of investment in buildings, quite apart from that of man-power. This aspect was emphasized even more markedly at Glasgow in a provocative paper, "The Economics of Education", by J. Wiseman, and it is also the theme of a recently published book by J. Vaizey on "The Costs of Education"*.

Mr. Wiseman is concerned first with the volume and nature of the resources devoted to education and with the most efficient use of those resources, postulating individual freedom of choice. He argues that we have accepted the role of the State as the provider of general education too uncritically, and that the place of educational provision in a free society needs re-examination. While his proposals are intended to achieve a more satisfactory allocation of our resources to education and at the same time meet better both the desires of parents and the interest of the community in education, they are too revolutionary and controversial to facilitate that steady and urgent improvement in matters of detail which at present seems to be the first need. The responsibilities of the State would still include, in his proposals, legislation requiring school attendance up to some minimum age and the maintenance of minimum standards; but for the rest, the contribution of the State would be limited to the provision of 'education vouchers' valid at any 'approved' school which the parents selected. The central government would accept sole responsibility for the financial share of the State, but local authorities would be allowed to charge fees if they wished and could. In the creation of new educational facilities, private building would be encouraged and public activity limited to what was necessary to make the system work.

Mr. Wiseman puts a point of view that merits consideration and might yet offer the soundest objective; but the immediate issues are too urgent to permit the long debate that would be necessary to secure the general agreement required before a policy based on his views could be formulated. Mr. Vaizey's study is much more practical. It provides in the first place the hard facts about the trend in educational expenditure in the United Kingdom since 1920. Moreover, as Prof. R. M. Titmuss observes in a foreword, the classification of this material by categories of resources, kinds of education and classes of beneficiaries allows Mr. Vaizey to comment trenchantly on current techniques of central and local control over expenditure, and the role of the teaching profession in the administrative structure. He sees, for example, a very strong case for relaxing the Ministry's detailed financial control.

Beyond this, existing weaknesses in the educational system of Britain, on some of which Sir Hugh Beaver commented forcefully earlier this year, are again displayed and pertinent questions about the rate of investment by the State in education are suggested; and the criteria discussed by which the real cost and value of education are to be judged—whether at the level of advanced scientific and technological training, or at that of primary and secondary education in the schools. Mr. Vaizey indicates the dangers which need particular attention and points out which investment is likely to bring a most effective return. Evidence may be found to support Mr. Wiseman's argument; but the great value of the study is the assistance which it brings to the identification of educational priorities. The determination of such priorities is a first duty if limited resources are to be wisely and efficiently expended, and for this such a factual survey is essential.

Even a few of Mr. Vaizey's broad conclusions suffice to indicate the need and value of a study in which the concept of cost is related to the national income. Until 1950, for example, expenditure, as ordinarily understood, on education involved a lower proportion of the national income than in most pre-war years; in 1955 it was less than in 1932, if such social expenditure as school meals, milk and the health service is excluded from the calculation. Even at 2·8 per cent, it compares with 2·2 per cent in the 1920's, 2·6 per cent in 1932 and 2·2 per cent in 1939; and including capital expenditure, the figure of 3·4 per cent compares with 2·7 per cent in

---

* The Costs of Education. By John Vaizey. Pp. 256. (London: George Allen and Unwin, Ltd., 1958.) 30s. net.

1930 and in 1938. Whereas in 1920 the central government provided 50 per cent of the revenue, local authorities 42 per cent and 8 per cent came from fees, in 1955 the corresponding figures were 58, 36 and 6 per cent.

Expenditure on public education in Britain rose from £84·6 million in 1921 to £168·1 million by 1946 and £410·6 million in 1955; but since 1945, rising expenditure has no more than kept in step with rising productivity. Over this period, while the proportion expended on primary education decreased from 42·8 to 30·7 per cent, that on secondary education increased from 17·7 to 22·3 per cent, on the universities from 5·2 to 8·2 per cent; that on further education remained constant at 6·0 per cent (after a decrease to 4·7 per cent in 1948 and a peak of 6·2 per cent in 1953) and that on the training of teachers rose from 0·4 per cent to 1·3 per cent. Between 1920 and 1955 the universities doubled their student population, and at 1948 prices their expenditure rose from £5·2 million to £25·4 million, with a doubling of expenditure in the seven post-war years and a 50 per cent increase in real terms, chiefly in consequence of the rising cost of scientific research and the greater amount undertaken. Moreover, the finding that university fees only represent one-seventh of the true cost has considerable bearing on current discussions on university awards.

Mr. Vaizey's study goes a long way towards supplying the perspective in which to judge current proposals for the expansion of particular aspects of education, such as the teachers' training colleges, the technical colleges and the universities, and also the soundness of the criticism advanced of such proposals, and of existing institutions and policy. In particular, it is apparent how important it is that no opportunity should be overlooked of ensuring both that the nation's steadily rising investment in education is wisely expended, and its distribution so timed as to secure the fullest return; and also that there is no waste of the trained man-power that results. Even when the utmost care has been taken to avoid waste of skilled man-power and to ensure that it is effectively deployed and supported with the technicians and ancillary workers and equipment necessary to ensure full efficiency, the production of the full number of scientists and technologists which are required to maintain Britain's industrial productivity will tax our resources to the utmost. No less care must be taken, therefore, to see that standards and conditions of teaching are such as to ensure the utmost efficiency, and to secure the fullest possible co-operation from industry and commerce, where the responsibility in what Sir Willis Jackson has rightly insisted is a partnership begins. In so far as the backwardness of particular firms or sections of industry in co-operating contributes to the waste of national resources and investment in education, the responsibility should be made plain, and if possible policy concerted to put the consequent cost where it properly belongs.

THE EDUCATION OF ADULTS

Adult Education

A Comparative Study. By Prof. Robert Peers. (International Library of Sociology and Social Reconstruction.) Pp. xiv+365. (London: Routledge and Kegan Paul, Ltd.; New York: Humanities Press, 1958.) 35*s*. net.

TWO years ago Prof. R. Peers retired after serving as head of the extra-mural department of the University of Nottingham for thirty-five years. He was then elected to a professorial research fellowship, and has since renewed acquaintanceship with various adult education movements in different countries, brought his knowledge of others up to date, pondered on the experiences of a life-time spent in adult education, and written this book. By clever design or skilfully arranged accident, the sub-titles on the dust-cover and fly-leaf are different. One refers to the work as a comprehensive study of adult education; the other to a comparative study. The author can fairly claim that he has written both.

The first part refers to the early origins of adult education in Great Britain and faithfully relates these to their social, economic, political and religious impulses. Then follows an account of the present characteristics of adult education in Britain to-day. This, as Peers freely admits, is almost entirely connected with the liberal adult education movement which has grown up under the auspices of organizations like the Workers' Educational Association and university extra-mural departments. Little or no mention is made of those informal activities which contribute so much to educational experiences in community life.

Peers then goes on to discuss the kind of student who makes up the liberal adult education movement and follows with a survey of the possibilities of adult learning. Foreign students of the British educational system who are bemused by the private nature of our public schools will be equally bewildered to learn that the Workers' Educational Association (and university extra-mural departments) to-day provide comparatively little for manual workers; members of trade unions are inadequately represented in their classes, and unskilled workers scarcely at all. The student body is largely middle and lower middle class.

The survey of adult learning is more concerned with the 'when' of learning than the 'how'. Peers's review shows how little is known of the learning process in adults and, after discussing the meagre information which does exist, indicates how his colleagues in the field could collect information which, when collated, might make considerable differences to the way in which adult education classes are conducted both inside and outside university walls. Although not agreeing with the zealots who believe that all adults are capable of continued education at an advanced level, Peers produces certain experimental evidence to support his own belief that, even among those who do not possess a high grade of generalized academic ability, there are specific abilities which can be developed throughout the life of the individual and which are perhaps no less important than those qualities of mind which have hitherto been given pride of place. Perhaps, inadvertently, Peers has again pin-pointed the need for investigations into the learning processes of adults of both sexes at different times of their lives and with different full-time educational backgrounds.

The comprehensive nature of this review of liberal adult education in Britain is rounded off with sections dealing with the place of tutors and the methods used in adult education. These bring out the relatively low status still accorded to extra-mural departments in many British universities; this may be connected with the fact that a number of extra-mural departments are still far from clear as to their own role either as a university department or in the educational movement as a whole.

The comparative study begins with a brief review of adult education in the Scandinavian countries, certain British Dominions and Japan; there is also an account of the not-too-successful attempts to form international organizations for adult education. Through his recent visits, Peers has gained up-to-date knowledge of adult education movements in the United States and Germany and rightfully devotes considerable attention to them. He suggests that in the United States the university extension movement is too all-embracing and popular; in Germany the universities are too academic and remote from the world at large to be of use to the ordinary man. With the British traditional liberal adult education movement based on the universities it is difficult to equate other systems with that of Britain; an Indian making comparative studies might come to different conclusions from those who have been steeped in the British way.

The concluding sections of the book contain the author's philosophy of adult education for a modern age. To this all-too-brief chapter one turns with full expectation of gaining much from the mature reflexions of one who has given so long and so generously to adult education. Nor is one disappointed. In contrast to the social and economic impulse which gave purpose to the early adult education movement in Britain and which helped to bring about many reforms in the national education system, Peers believes that the future of adult education will no longer lie in providing belated opportunities for learning which the community has failed to provide at the proper time. Instead, the purpose of continued education in adult life is seen as a necessary part of the education of the citizen of the democratic State, "that part which *belongs* to adult life because it cannot be undertaken at any earlier stage". Adult education should, therefore, be available for all who are capable of profiting by it, and Peers is undoubtedly right in stating that this number is very much greater than those who are taking advantage of the opportunities available at present.

Whether he rightly appreciates the part which existing adult education organizations will play in the educational activities of future adults remains to be seen. Despite the insidious onset of Admass, the extension of television has led to 'full houses' at theatres where ballet and opera are performed. Current political and social problems are discussed by more people in industrial canteens than many who are not daily in touch with the working man are prepared to believe. Many industrial education officers are also aware of the extreme suspicion which intelligent shop-floor workers have of any movement which savours of the academic or institution. Using the interests created by television, the extension of adult education may take place most freely in conjunction with the growth of more informal activities provided in places where men work or spend their leisure. In this, science must have a much greater place than hitherto; this can only come about if more of our adult educationists are themselves men of science. Whatever the means of the spread, there is little doubt that all who are concerned with the true ends of adult education will gain from Peers's all-too-short account of the future in adult education. They will also benefit from a remarkably well-written book which is both comparative and comprehensive.

T. H. HAWKINS

THE HAND AND HUMAN NATURE

The Human Hand

A Psychological Study. By Géza Révész. Translated by John Cohen. Pp. xii+138. (London: Routledge and Kegan Paul, Ltd., 1958.) 21*s*. net.

AS a leading theme for the attention of psychologists interested in trying to relate the highest attributes and capacities of man to their biological foundations, the human hand presents notable advantages. It is indeed surprising how little serious work has been devoted to it. Along with high-grade sensory functions and a massive reorganization and development of the brain, it is a central feature of the sequence of adaptations which eventually placed man in a position in many respects dominant among animals. It is at once an important sense-organ and a tool of far-reaching potentiality. But at the same time it crops up in a host of interesting, and sometimes suggestively odd, connexions in myth, religion and custom, and in artistic and symbolic expression. The activities of this one part of the body are thus embedded in every level of human behaviour, and to trace in continuous fashion their inter-relations could scarcely fail to illuminate more general problems of human nature.

Yet up to the present, helpful contributions to the subject have been limited in scope to special aspects. Sir Charles Bell seems to have found insufficient material to fill his "Bridgewater Treatise" of 1833, for it contains much on other topics. Later anatomists whose vision extended outside the dissection-room, notably Wood Jones and Elliot-Smith, did much to elucidate the role of the hand in human evolution, the latter especially in relation to the emergence of complex cerebral organization and refinements of the distance-receptors. Its connexions with the origins of language, including as they do many puzzling issues concerned with handedness and cerebral dominance, remain obscure despite a lot of attention from clinical neurologists and others during the past century. Studies of gesture language have tended to oscillate between pure description and wild speculation. On a rather different plane there have been persistent attempts to formulate and generalize intuitive connexions between the physical form of the individual hand and the character and temperament of its owner. An absence of coherent scientific structure in such speculations makes decision as to their merits more than difficult.

It was to direct attention to this fascinating and potentially rich field that the late Prof. G. Révész wrote this engaging little book, now skilfully and sympathetically translated by Prof. John Cohen. Révész's own interest grew out of his studies in tactile perception and in the artistic capacities of blind people. But, apart from a rather strange failure to refer to the forms of breakdown of the perceptual and executive powers of the hand produced by cerebral disorder, he touches on most aspects of the subject. Inevitably in so brief a work his touch is light. There are chapters on the comparative and developmental aspects ; these suffer somewhat from lack of reference to the central nervous functions without which the hand itself would be inert and useless. Some varied points concerned with the general significance of the hand in human life are interestingly sketched, and the bulk of the book is devoted to discussion of specific functions such as perceiving, manipulating, plastic activity and expression. The book ends with a short and stimulating chapter on the magical significance of the hand. Prof. Révész is never dull, if not always satisfying. He has sketched a field worthy of a much larger work. There are a number of nice pictures. Perhaps this is why a guinea has had to be charged for scarcely forty thousand words of text.

R. C. OLDFIELD

SCIENCE IN AFRICA

Science in the Development of Africa

A Review of the Contribution of Physical and Biological Knowledge South of the Sahara. By Dr. E. B. Worthington. Pp. xix+462. (London: Commission for Technical Co-operation in Africa South of the Sahara, and the Scientific Council for Africa South of the Sahara, 1958.) 30*s*. net.

TWENTY-FIVE years ago many of those concerned with developments in Africa felt that progress was impeded because there was no overall account of conditions in the various territories. One result was Lord Hailey's "African Survey", first issued in 1938 and fully revised in 1956. Dr. Worthington, also in 1938, produced his "Science in Africa", designed to supplement Lord Hailey's volume. The book now issued is a revised, rewritten and expanded successor to the earlier work.

Particularly since the end of the War in 1945, organizations have grown up to foster co-operation in the African territories. Dr. Worthington was the first secretary-general of the Scientific Council for Africa South of the Sahara, and it is on behalf of that Council and of the Commission for Technical Co-operation in Africa South of the Sahara that this book is issued.

Parallel with the great political developments which have taken place in Africa since 1938 the scope of scientific work has increased immensely, so it was clearly a monumental task that Dr. Worthington undertook when he attempted to condense all this into a book of less than four hundred pages of text. Only a man with his experience of Africa, as a research worker and as an administrator of science, could have done this. There is some account of every major, and many a minor, project in the physical and biological sciences in all the territories concerned. In all the cases in which I have any knowledge the information given, so far as it goes, is accurate and carefully checked, and what might have been a list of disconnected statements is turned into a readable story. This should be of considerable value to anyone who wants to obtain a bird's-eye view of scientific developments in the continent of Africa.

We are shown how scientific organization has increased, facilities have improved, and research has developed. At times the reader may feel that with still a comparatively small number of investigators in the field or at the bench, the organization is somewhat top-heavy, and it is difficult not to sympathize with the view often expressed by actual research workers that some of the resources expended to encourage co-ordination would be better used to support original work. Also, while there have been noteworthy applications of some of the discoveries, science has still made little contribution to the increase in productivity in many of these countries which must take place if the ambitious plans of politicians are ever to be implemented. The hope of those who set up the Scientific Council was that, by international co-operation, these developments might be accelerated.

The reader who will be most disappointed with this book is the one with a specialized knowledge of some particular problem. Dr. Worthington has had to cover such a wide field that many subjects are inevitably given sketchy and incomplete treatment. Numerous examples could be quoted. For example, though there has been a great deal of research on poultry-keeping in the tropics, here we find only ten lines of very general information in the section "Other Kinds of Stock", and two lines on Newcastle disease in the section on "Virus Infections". In another context the importance of medical training of indigenous people is referred to, but there is no mention of the ambitious medical school at Dakar, allied to the Universities of Bordeaux and Paris, or of the teaching hospital at Ibadan in Nigeria, though this must be the largest and best equipped building devoted to scientific work in the African tropics. Such deficiencies do not, however, greatly detract from the value of the book to the reader who wants only a general picture, and the bibliography may help those who wish to study particular topics more fully.

Dr. Worthington believes, as do the members of the bodies which sponsor this work, in inter-territorial co-operation. He concludes (after briefly sketching the progress of scientific work) with these words: "In the 1950's the territorial and regional barriers are breaking down through inter-African co-operation. By the 1960's we may see African science taking its full and proper place in the development of the continent". While echoing this final hope, there would seem to be some doubt as to whether the barriers are in fact breaking down. Elsewhere Dr. Worthington mentions that nationalism and tribalism, by dividing larger colonial territories into smaller self-governing States, may discourage scientific co-operation. I am inclined to think that these inevitable changes may not, in the long run, be very important. African scientific development has reached a stage where co-operation cannot be forced on it, any more than it could on the various countries of Europe. Some territories "South of the Sahara" have as much in common with countries in Asia or America as with their neighbours. Dissemination of information about scientific work in Africa, as in other areas, is now probably best through the normal international channels. Artificial regionally based organizations may well be obsolescent.

This revision, after twenty years, of Dr. Worthington's survey of 1938, is perhaps of greatest value in showing that science in Africa is growing up. As the countries of Africa take their place in the international field, specifically 'African science' is seen to be something of a myth, and we have now to deal simply with science—which is now being studied in the African continent.

KENNETH MELLANBY

TROPICAL FOREST ARCHÆOLOGY

Archæological Investigations at the Mouth of the Amazon

By Betty J. Meggers and Clifford Evans. (Smithsonian Institution: Bureau of American Ethnology, Bulletin No. 167.) Pp. xxviii + 664 + 112 plates. (Washington, D.C.: Government Printing Office, 1957.) n.p.

THE authors of this report studied an extensive area consisting of the islands of Marajó, Mexiana and Caviana at the mouth of the Amazon, and the territory of Amapá which lies north of it. It is an area in which living conditions are far from pleasant and transport can be excessively difficult. The natural conditions are a great hindrance to archæological work, but the authors overcame them with great determination.

The area was previously known only for the remarkable pottery burial urns and associated objects belonging to what is now called the Marajoara Phase on Marajó Island, whence have arisen theories that the island was a centre of cultural development, radiating its influence far and wide. The expedition proved that the truth was the precise opposite; not only were seven more lowly phases of culture shown to have come fully fledged into the area and to have maintained themselves at their initial level until absorbed or displaced by the next invader, but also the more elaborate Marajoara Phase was demonstrated to have arrived similarly and at once embarked on a process of degeneration, ending up at the same level as the others. Most of the objects belonging to the living tribes of the lower Amazon are very perishable —wood, gourds, feathers and so on—and they soon disappear when discarded, leaving only pottery and rare objects of stone. The same conditions undoubtedly existed in antiquity, and the present work is of necessity based mainly on pottery, but the application of the most rigorous and painstaking methods of analysis enabled much to be learnt. In this connexion attention must be directed to a misprint in Fig. 141 which vitiates an argument, the pottery titles Inajá Plain and Camutins Plain having been interchanged.

The main outlines of the authors' conclusions have been known for some time to specialists through short communications, and what this report does is to set out the evidence fully and state some of its wider implications. Some years ago, Julian Steward gave strong support to the theory that a tropical forest could only support a culture on what he called the 'Tropical Forest' level, similar to that of the living forest tribes, and that a more advanced culture coming in would, owing to limitations of food supply, decline to tropical forest level. The authors see the behaviour of the various cultural phases, and particularly the decline of the Marajoara Phase, as a triumphant vindication of this theory. In addition, they have developed an ingenious method of building up a time-scale by means of the rate of accumulation, not of deposits but of potsherds; they themselves realize the limitations of this, but it seems to work on the whole, and it gives an indication that the earliest pottery-making tribes in the islands cannot have arrived before about A.D. 700, whereas the mainland of Amapá was not occupied by such people until much later. A further conclusion is that the archæological record does nothing to support the theory that the tropical forest pattern of culture spread from the north down the Guiana coast and up the Amazon. By a study of the distribution of traits the authors have indicated probable sources for the various phases, and in particular they believe that the Marajoara Phase originated in the Andean areas of Ecuador and Colombia.

A point which has already involved the authors in controversy is their contention that the way in which a tropical forest environment limits a culture constitutes a law of universal application, not confined to the area where they have applied it so successfully. The Maya appear to be a notable exception, and although Meggers has maintained that they did not develop their high civilization in the tropical forest part of their habitat, many Maya specialists disagree, and whatever their origin, the Maya succeeded in maintaining their culture there for a long time. Parts of the Old World, such as Nigeria and south-east Asia, would repay further study in this connexion. G. H. S. BUSHNELL

BIRDS IN SPAIN

Portrait of a Wilderness

The Story of the Coto Doñana Expeditions. By Guy Mountfort. Pp. 240 + 59 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1958.) 30*s*. net.

MANY people saw and enjoyed Mountfort's beautiful colour film, "Wild Spain". His present book gives a report on the expeditions to Coto Doñana, where the film was made. There were three expeditions (in 1952, 1956 and 1957), the last one being the largest and best equipped. All of them consisted of qualified students and experienced photographers, and since the main interest was in birds, the ornithological staff of the expeditions was well selected, the names of the members speaking for themselves.

Coto Doñana, a wonderful spot on the Atlantic coast of Andalucia, is truly a bird paradise of incomparable beauty and richness of bird and animal life. Since the fifteenth century it has been known as a famous hunting ground of the kings of Spain, and, owing to the efforts of its successive owners, it has preserved its unique character of a wilderness unaltered and undevastated by man, where plants and animals live freely and undisturbed by modern civilization. In addition, it lies in a very favourable part of the continent of Europe from the point of view of natural history phenomena, and this makes it one of the most interesting nature preserves in Europe. During the spring migration the numbers of birds and species represented are incomparable. Some rare birds breed there, others appear periodically during the migration.

The aims of the expeditions were to study birds, to photograph them, as well as to collect materials referring to other zoological groups. In this respect they were successful also, and the collections made will add valuable scientific information about this area. The birds, however, are the main objective of the present book and they are described with love, zeal and pure scientific exactitude. It is the author's great merit that, writing on scientific matters and observations, he does so not only in very simple and readable manner but also with humour and much interest. Consequently, his book is by no means a dry and scientifically overloaded account digestible by specialists only. On the contrary, it will be greatly enjoyed by everyone interested not only in birds but also in general zoology, geography, folklore and so forth. These values, together with the author's literary abilities, have resulted in a beautiful book which will be read by everyone, not only with profit but also with great pleasure.

Special mention must be made of the photographs illustrating the text. Most of them were made by Eric Hosking, a name that speaks for itself. All are at the highest level of technical and ornithological skill and talent—they are simply wonderful. The ornithologists of the expeditions were fortunate enough not only to watch some very rare species but also to photograph and film them. Photographic material collected by the expeditions contains pictures of species that have never before been photographed. Some of these unique scientific documents are included into the book, others could be seen on the colour film already mentioned.

Many black-and-white drawings by Penelope Mountfort and the author himself add much charm to this tastefully edited and executed book. It should not only be recommended; it certainly will be a desirable and greatly enjoyed acquisition in every library. W. RYDZEWSKI

ELECTRODYNAMICS OF MOVING MEDIA

Electromagnetism and Relativity with particular reference to Moving Media and Electromagnetic Induction

By Prof. E. G. Cullwick. Pp. xxiii+300. (London and New York: Longmans, Green and Co., Ltd., 1957.) 63*s.* net.

THERE is a need in the literature, the author reminds us in the preface to his book, for a systematic study of the electrodynamics of moving media. The title of the volume under review leads one to expect that this need would be met by Prof. Cullwick's book. Unfortunately, it disappoints, and leaves the impression that the author has been primarily concerned with elucidating a familiar theory by a number of isolated problems some of which are now classical.

The book does not lack general interest; but certain misleading and controversial conclusions do much to detract from its value as a reference book. The book is divided into four parts and it will be convenient to deal with each in turn. The first part is concerned with the uniform rectilinear motion of charged particles and moving media, and includes chapters on special relativity and the relativistic transformation of Maxwell's equations. Earlier chapters in this part summarize some elementary results in electricity and include a discussion of the definitions of electric and magnetic forces in polarized media. The treatment here differs in several important respects from that usually found in treatises on electricity and appears to be unnecessarily involved. It leads to the curious, though correct, conclusion that the polarization vector, as defined in this book, should vanish for a conductor under the influence of an electrostatic field.

It would have been more logical and instructive to have deduced the first-order effects of charges in uniform rectilinear motion from the relativistic formula derived in the chapter on relativistic electrodynamics instead of devoting a separate chapter to the subject. Again, in his account of the advent of the theory of relativity, Prof Cullwick specially singles out Poincaré's work, and in this respect appears to follow the lead given by the late Sir Edmund Whittaker in his "History of the Theories of the Aether and Electricity". Prof. Cullwick also dissents from the generally accepted explanation of the so-called 'clock paradox' in relativity and allies himself with Prof. H. Dingle in this controversy.

The second part of the book is on electromagnetic induction. Here the author appears to have been more successful, and the reader will find much that is useful. The distinction between electromotive force and potential difference is well drawn and illustrated by interesting examples. Likewise, the essential difference between the problem of a non-magnetic conductor rotating in an external magnetic field and the problem of a magnet rotating about its axis is made clear and is instructive. Prof. Cullwick has also rightly included in this part brief accounts of Bullard's theory of the maintenance of the geomagnetic field by dynamo action, and of magnetohydrodynamic waves. A fuller account of this new science, especially the parts which are essentially theorems in electrodynamics, would have enhanced the value of the book.

The third part of the book relates to the relativistic theory of second-order electromotive forces in moving circuits. A simple relation is shown to exist between the measurement of induced electromotive forces in systems in uniform relative motion, and this relation is illustrated by well-designed examples.

The fourth part is devoted to electromagnetic energy and momentum of moving systems. After discussing the reasons for introducing the Poynting and electromagnetic momentum vectors to retain the conservation laws of energy and momentum, the author devises examples to illustrate systems in which ponderomotive forces are 'unbalanced'. The reviewer, however, found the discussion here obscure and involved.

Prof. Cullwick also appears to be under a misapprehension about the nature of the magnetic energy of a system of electric currents. On p. 260 we read that "the hypothesis is introduced that the magnetic energy of a current circuit is the same as the kinetic energy of the effective conduction electrons, by virtue of their mean velocity along the wire". The author then derives from this hypothesis a linear relation between the magnetic vector potential and the mean velocity of the charges, this relation involving an "effective mass" which is left undefined. The reviewer is unable to agree with the findings of the author, and the hypothesis appears to be rather misleading. It is used in the chapter on superconductors to derive the familiar equations due to F. and H. London. Here the application is legitimate and indeed the linear relation mentioned above was first derived in connexion with the phenomenological theory of superconductors. But the relation cannot be universally true since it would seem to carry with it the implication that all conductors are superconductors.

To sum up, there is much that is of value and of interest in this book, but for reasons given in this notice, the book cannot be recommended unreservedly.

V. C. A. FERRARO

Tables of Partitions

Initiated and Computed by Hansraj Gupta. Computed Independently by C. E. Gwyther and J. C. P. Miller. (Royal Society Mathematical Tables, Vol. 4.) Pp. xxxix+132. (Cambridge: At the University Press, 1958. Published for the Royal Society.) 63*s.* net.

THIS is undoubtedly the most comprehensive tables of partitions ever published. The principal function tabulated is $p(n,m)$, the number of partitions of the positive integer n into at most m integral parts (or into integral parts none of which exceeds m). Table 1, occupying 87 pages, gives $p(n,m)$ for $n = 1(1)200$, $m = 0(1) \min (n, 100)$ and for $n = 200(1)400$, $m = 0(1)50$. Table 2, of 32 pages, is intended for use as an auxiliary table, by means of which $p(n,m)$ can be calculated readily for values of m not given in Table 1. It gives values of $p_2(n,m)$ for $n \leqslant 1{,}000$, the maximum value of m varying from n for $n \leqslant 50$ to 0 for $500 \leqslant n \leqslant 1{,}000$. Here $p_2(n,m)$ is the number of partitions of n into parts consisting of two varieties of integers not exceeding m and one variety of each larger integer; in particular, $p_2(n,0) = p(n)$, the number of unrestricted partitions of n. A third table, of ten pages, tabulates a range of values of $p_3(n,m)$, the number of partitions of n into parts consisting of three varieties of integers not exceeding m and two varieties of each larger integer. The range is $n = 1(1)50$, $m = 0(1)n$; $n=50(1)100$, $m=0(1)19$; $n=100(1)150$, $m=0(1)6$; and $n = 150(1)200$, $m = 0$. The final tables gives $p_4(n,0) = p_3(n,n)$ for $n = 1(1)200$.

The introduction gives an interesting review of the extensive literature on these functions, and in particular of explicit formulæ for $p(n,m)$ as function of n for fixed m ($m \leqslant 12$). It concludes with a description of the method of construction of the tables, in which, in the fourth line from the foot of p. xxxiv, $p_1(n) = p_2(n,0)$ should read $p_2(n) = p_3(n,0)$.

The rather tricky problems of layout in a table of double entry involving large numbers have been ingeniously overcome, and the tables should be easy to refer to.

J. A. TODD

Set Theory

By Felix Hausdorff. Translated from the German by John R. Aumann *et al.* Pp. 352. (New York: Chelsea Publishing Company, 1957.) 6 dollars.

HAUSDORFF'S famous work, "Grundzüge der Mengenlehre" (Leipzig, 1914), needs no introduction to the pure mathematician. In the third edition the first nine chapters are an almost unchanged reprint of the second edition. A tenth chapter has been added, dealing with the Baire condition for sets and for functions, the restricted Baire condition, and with half-schlicht mappings. This is a valuable and interesting addition.

R. G. COOKE

Linear Programming and Economic Analysis

By Prof. Robert Dorfman, Prof. A. Samuelson and Prof. Robert M. Solow. (The Rand Series.) Pp. ix+527. (London: McGraw-Hill Publishing Company, 1958.) 77*s.* 6*d.*

THIS book is one of the series presenting the results of research by the Rand Corporation. It is intended for economists who wish to learn something of recent developments in the application of mathematics to economics. The first few chapters present the method of linear programming, with some applications worked out in detail, and the special methods available for transportation problems. There is a chapter on non-linear programming and two chapters on input–output analysis as developed by Leontief. Other chapters deal with dynamic aspects of linear models and with programmes for capital accumulation. An essential idea here is optimization over time. Linear programming is discussed in relation to the theory of general equilibrium and to welfare economics. Finally, there are chapters on the theory of games and its relation to linear programming. These last chapters are added for the sake of completeness, and this is the only justification, for, as the authors point out, ". . . the 13 years that have elapsed since the publication of the "Theory of Games" (by von Neumann and Morgenstern) have seen no important applications of game theory to concrete economic problems".

The reader should find the book easy going, for the exposition is nowhere concentrated and the impression is that the authors have been allowed as many pages as they desired. This allows detailed explanation and the inclusion of many fully worked examples. But it also makes the book expensive and it means that the reader will have to spend a long time absorbing relatively little. The reviewer feels that the rate of communication between the authors and the reader will be too slow to be very satisfying. It might have been better to have said as much in fewer words.

L. S. GODDARD

Salmonellosis in Animals

By Dr. A. Buxton. (Review Series No. 5 of the Commonwealth Bureau of Animal Health.) Pp. vii+209. (Farnham Royal: Commonwealth Agricultural Bureaux, 1957.) 25*s.*

THIS book is a review of salmonellosis in animals, and, in particular, of the vast literature which has accumulated from 1888 to the present day on the many aspects of this subject. The author has been careful to include information from field studies and the natural history of disease as well as from the laboratory and the experimental work; he has interpreted these in relation to the naturally occurring disease.

A chapter is devoted to technical methods of classification of the Salmonella group of organisms, of which more than 500 have been described. Reference is made to certain details of antigenic structure, their possible relationship to virulence, and the effect which certain minor variations in the structure of the organisms have had on the detection of infection in the field.

The distribution of Salmonella serotypes among the various animals, birds, reptiles, insects, and ticks, summarizes our present knowledge. The epidemiology is well covered; obviously the author has been personally concerned with this aspect. Careful consideration is given to general aspects such as the state of the host, its diet and environment and the influence such factors exert on clinical infection.

Many problems remain unsolved in the animal disease; as yet there is no final proof of the value of vaccines or of antibacterial substances. The author is to be congratulated on bringing into one book so much information, previously available only in scientific journals; also for including data on wild and unusual animals so often neglected in the text-books.

JOAN TAYLOR

NUCLEAR POWER AND THE ENGINEER*

By Sir CHRISTOPHER HINTON, K.B.E., F.R.S.

ALTHOUGH in a narrow sense nuclear power has only introduced an alternative fuel, much more than this has been done since 1946 when the Atomic Energy Organization of the United Kingdom was first formed within the Ministry of Supply: a whole new and complicated industry has been created. The first factory, which was built at Springfields, was for the extraction of uranium from its ore and the subsequent purification of the uranium salts and their conversion into metallic uranium, which was enclosed in cans for insertion into the reactors. After irradiation in the atomic piles, these fuel elements contained plutonium, which was needed for defence purposes, and a reduced quantity of uranium-235. They were treated in chemical plants, in which the plutonium was extracted in an impure form and afterwards purified and converted into ingots of metal. The solution containing fission products was concentrated by evaporation and put into storage, while the uranium, with its depleted content of uranium-235, was purified. Before it could be re-used in reactors this depleted uranium had to be re-enriched in its fissionable isotope, and this was done in the diffusion plant which was built at Capenhurst.

In the ten years between 1946 and 1956 the problems of these ancillary plants were inconceivably greater than the problems involved in the design and construction of nuclear reactors, and of all the difficulties which we met during those years I believe that those connected with the design and construction of the chemical separation plants were by far the greatest. But these plants are likely always to remain behind the scenes; it seems probable that they will continue to be operated by the Atomic Energy Authority, and as each plant is able to process the materials required for, and produced by, several reactors, the number of these plants is likely to be limited. It is in the development and use of the reactors themselves that public interest has been mainly concentrated, and it is in this field that the greatest development is likely to take place in the future.

One of the reasons why the reactor problems presented the least of all our difficulties in those early days was that in designing them we were able to proceed in a stepwise way towards the evolution of advanced systems, whereas in the development of the ancillary processing plants we were bound to jump directly from laboratory-scale work to the design and construction of full-scale units planned to meet the requirement for many years ahead. When, in 1946, we started to design the graphite-moderated, air-cooled experimental reactor at Harwell, we had the benefit of the experience which had been gained through participation in the design of the Chalk River experimental pile, and the fact that even to-day this is probably the best general-purpose research reactor in the world is a tribute to the skill and ingenuity of Newall and Ginns, who were mainly responsible for its engineering. It consists simply of a mass of graphite moderator built up from accurately machined blocks in which rods of uranium enclosed in aluminium cans lie in a suitably spaced lattice. The heat of fission is removed by blowing air over the uranium rods and the heated air is passed through filters and discharged to atmosphere. The reacting core is enclosed within a concrete biological shield and control is exerted by moving rods of boron steel (which is an effective absorber of excess neutrons) into the reacting core through one of the biological shield walls.

The experience which was gained in designing and building BEPO was extremely valuable. At first it is worrying to feel that one is designing a complex and expensive plant where, if breakdown occurs, it is impossible to get access for repairs. This feeling led to a standard of accuracy in the construction of BEPO which was not justified. Indeed, the most important experience which we gained in carrying out this project was the knowledge of how far it was possible to depart from the theoretical requirement stated by the scientist while still meeting his practical requirement. This is the basis of all engineering art.

Our next commitment was to build the large reactors required for plutonium production for defence purposes. It was at first intended that these should be of a design similar to those at Hanford in the United States, that is, thermal reactors, graphite-moderated and water-cooled. But at that time it was not possible to build reactors of this type which had inherent stability. During operation they might become super-critical and disperse radioactive fission products over a fairly large area of the countryside. Because of this, the Americans had located their reactors in a remote situation, and had adopted safety distances from towns of various sizes. There was no evidence at the time to suggest that these safety distances could be relaxed, which made it difficult to select convenient sites in a densely populated country like Great Britain.

We know that during the War the Americans had wished to build a large gas-cooled reactor but were discouraged by the difficulty of obtaining the huge blowers that were required. The attractions of gas-cooling were, however, so great that we started an intensive study of the problem. We came to the conclusion that by putting fins on the cans of the fuel element and by compressing the coolant gas we could design gas-cooled graphite-moderated reactors which would not only produce plutonium but would also at the same time generate electrical power. Power could not be generated, however, unless the temperature of the gas leaving the reactor was reasonably high, and the problems of achieving these temperatures involved more research than we had time for. We realized that by temporarily sacrificing our objective of generating electrical power and by using air at atmospheric pressure as our coolant we should be able to build a reactor for the production of plutonium which would be inherently safe and which would not need to be built in a remote locality. This led to the construction of the Windscale reactors, which are, in fact, scaled-up versions of the large Harwell experimental reactor which we had already built.

---

* Based on a discourse delivered to the British Association on August 29.

The scale of the construction can be judged by the fact that the chimneys are more than 400 ft. high and the total weight on the foundations was about 58,000 tons. But, apart from their scale, they represented only a reasonable step forward from the practice which had been evolved in designing the Harwell experimental reactor. The most important development as compared with Harwell was in the introduction of burst slug detector gear. It was only at a comparatively late stage in the design that the need for this gear was established and the technique for detection was evolved. This technique involves taking samples of the exit air from all of the channels in the reactor so that, if a defect develops in any of the fuel elements, the fission products which escape can be deposited electrostatically on a wire, which is then monitored by a Geiger counter. It was impossible to sample the exit air from all channels without introducing moving parts to the reactor. The guiding principle in all our design philosophy had been to avoid any moving parts within the active zone, and the decision to use this air-sampling gear was a difficult one, but in spite of it the essential simplicity of the design remains.

Meanwhile, we continued to work on the problem of developing a gas-cooled reactor for the production of useful power. By 1953 we had arrived at a practical scheme. In that year there was an additional demand for plutonium for defence purposes and we decided that this requirement should be met by building graphite-moderated gas-cooled reactors which would produce electrical power as a by-product, and this was done on the Calder Hall site.

In the Calder Hall reactors the heat of fission is removed from the fuel elements by cooling them in pressurized carbon dioxide gas instead of with atmospheric air as in the Windscale reactors. The uranium fuel elements are arranged vertically in the mass of the graphite moderator and the whole of the reactor core is enclosed in a steel pressure vessel which is more than 40 ft. in diameter. Hot gas leaving this vessel is passed through ducts to the heat exchangers, in which it gives up its heat to water and so generates steam, which is used in conventional turbo-generators to make electric power. The carbon dioxide gas cooled in this way passes through other ducts to the blowers, which force it back once more into the reacting core.

When the construction of the first Calder Hall reactor was only in its early stages we felt certain that it could form the basis of the programme for the large-scale development of industrial nuclear power, and this scheme was published in the White Paper of 1955.

Up to that time all British nuclear power plants had been designed, built and operated by the Atomic Energy Authority, although all the component parts had been manufactured by industrial firms. It was decided that this was the appropriate stage at which industry ought to be brought in and trained in reactor design so that the Atomic Energy Authority could proceed with its main task of developing more advanced types, while the industrial firms built the reactors which would be used by the electricity supply authorities. Four of these industrial power stations are now being built.

The electrical output of these industrial reactors will be far greater than that of the Calder Hall reactors. In the Bradwell reactor the pressure vessel which contains the reacting core has been made spherical and is of considerably greater diameter; a larger core is thereby made possible and heat transfer is improved by using a higher pressure in the circulating carbon dioxide. But essentially, the principles of design of this reactor and of the other reactors which are being built for industrial use are identical with those which were evolved for Calder Hall and which have now been in satisfactory and uneventfu operation for two years.

When I gave the Clayton Lecture to the Institution of Mechanical Engineers in February 1954, I said: "In looking at the Windscale piles you will be struck by their essential simplicity. This is, indeed, the key to pile design. The problems as initially presented to the designers rarely looked simple, sometimes they looked almost frightening in their difficulty and more often they were frightening in their high content of the unknown. The main skill in pile design has been in reducing such problems to terms in which they could be interpreted into engineering structures so simple, so well understood, that even the unknown ceased to give cause for alarm". This is true to-day of all good reactor design; in looking at the designs of Calder Hall and of the industrial reactors the most striking feature is once more their simplicity, and simplicity in reactor design must always be achieved. Simplicity is the essential of all good design.

Having looked at the course of reactor design since it started in 1946, let us try to predict its future. We have seen that in our earliest reactors, though we released large quantities of heat, we were not able to use this heat for the generation of a useful electrical power because we could not recover it at a sufficiently high temperature. By the time that the design of Calder Hall was put in hand, developments in research had made it possible to achieve temperatures which enabled us to generate useful power, but these temperatures are still low by comparison with conventional power plant practice.

If we look at the history of these conventional power plants we find that their capital cost has steadily fallen with the passage of years. More than anything else this reduction in the capital cost of steam power plants has been linked with the rise in the initial temperature which it has been possible to achieve in the steam cycle. This rise in initial temperature with the passage of time is shown in Fig. 1. The limit has been imposed by different factors at different times: in the earliest days it was controlled by the pressure which could safely be sustained in cast-iron vessels; later it was limited by the performance of cylinder lubricating oils in reciprocating engines; but for the past forty years it has been controlled by the metallurgy of the materials available for superheater, steam pipe and turbine construction. This rise in the initial temperature in the steam cycle has made it possible for higher working pressures to be used, and this in turn, operating hand in hand with other developments, led to bigger boiler and turbine units, and it is this growth in unit size and rating which, more than anything else, has brought down capital costs. But besides bringing down the capital cost of conventional steam plants, the higher top temperatures which have been achieved in the steam cycle have increased the efficiencies which have been achieved. James Watt's engines consumed 6 lb. of coal per horse power hour; to-day the modern

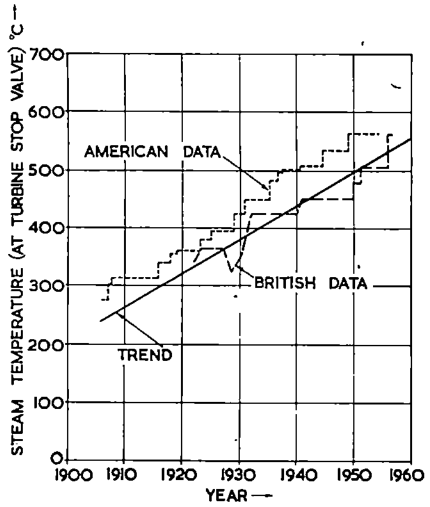

Fig. 1*a*. Rise of steam temperature with passage of time

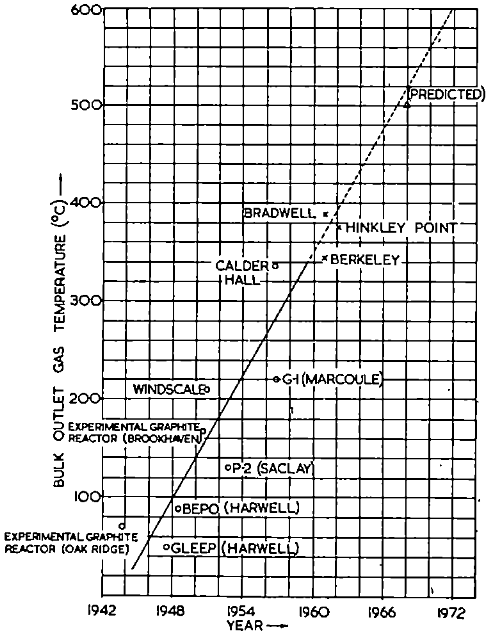

Fig. 1*b*. Rise of outlet gas temperature with passage of time

steam generating plant consumes only ¾ lb. of coal per horse power hour, and this rise in efficiency has sprung almost entirely from the rise which has been possible in the initial temperatures in the heat cycle.

When the Windscale reactors were built we were not able to recover the heat of fission at a high enough temperature to enable us to generate any useful electrical power. The considerations which held us down to these low temperatures were the possibility of reaction between the graphite moderator and the cooling air and, secondly, the possibility of trouble with the fuel elements. These fuel elements consisted of rods of uranium metal about 1 in. in diameter enclosed in aluminium cans. Aluminium was used as the canning material mainly because it has a low cross-section for neutron absorption; magnesium was considered as an alternative material but was rejected because of the possibility that the cans might catch fire and cause great damage. But while the use of aluminium had the advantage of avoiding this difficulty, it had the corresponding disadvantage that it was known that aluminium formed a metallic compound with uranium and that this chemical reaction proceeded more rapidly as the operating temperature rose; and it was mainly this consideration which held us down to the temperatures which were used in the Windscale piles.

The construction of the Calder Hall reactors, in which the heat of fission was recovered at a sufficiently high temperature to enable it to be used to generate useful electrical power, was made possible mainly by researches which overcame this difficulty. An alloy of magnesium was developed which made the possibility of the ignition of the can much more remote, and in addition, the use of carbon dioxide as a coolant instead of air still further reduced the risk of fire. Since that date the experience which has been acquired in the fabrication and use of fuel elements of the Calder Hall type has made it possible to assume in the design of the reactors for the electricity authorities that it will be possible to achieve temperatures slightly higher even than those which are used at Calder Hall. We find, then, that the short history of nuclear power shows an upward trend in the top temperature which can be achieved from our reactors in exactly the same way that we find that the much longer history of conventional power plants shows an upward trend in the top temperature of the heat cycle (Fig. 1).

Besides the top temperature which can be achieved in the cooling gas leaving the reactor, there is another major factor in reactor design which affects the capital cost per kilowatt of power produced. This is the rating of the fuel elements. If the rating of the fuel elements can be doubled (that is to say, if twice as much heat per second can be produced from each kilogram of uranium in the reactor) then obviously twice as much heat and approximately twice as much power can be produced from a reactor of given size and the capital cost per unit of heat output will thereby be reduced. There are many factors which affect the fuel element rating which can be adopted, but of these the most important is the temperature at the centre of the uranium fuel element. The heat of fission is generated throughout the whole mass of uranium and the heat released in the centre of the fuel element must be conducted to the surface for removal in the stream of cooling gas. This flow of heat demands a temperature gradient, and it therefore follows that the temperature of the centre of the uranium rod must be higher than the temperature at its surface. The higher the rating of the fuel element, the greater must be the temperature gradient across it in order to conduct heat from centre to surface. Higher fuel element ratings, therefore, mean higher centre temperatures in the uranium and, when this is accompanied by the higher surface temperatures which are necessary in order to enable us to achieve higher temperatures in the exit cooling gas, we soon find that we are operating at uranium temperatures which are likely to be troublesome. But Fig. 2 shows how fuel element ratings have risen in the past, and if reactor technology is to continue to develop in the future this trend must be continued.

We are therefore faced with the conclusion that improvement in industrial nuclear power plants can only be made possible by increasing top temperatures and the heat ratings of our fuel elements and that this demands fundamental development in fuel element design. These developments involve research

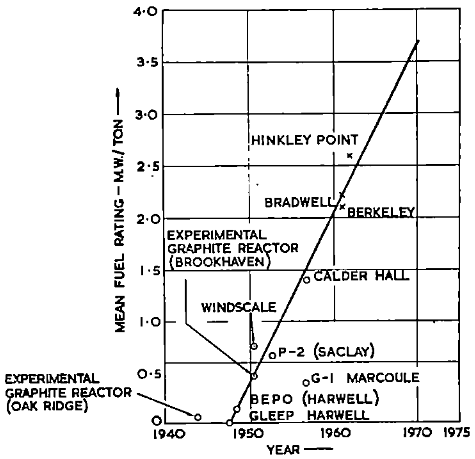

Fig. 2. Rise in fuel rating with passage of time

which is largely of a metallurgical character, and so once again in the nuclear field we find that, as has so often happened in the development of conventional power plants, the engineer must rely on the metallurgist for research and development work before he can make real progress. In my 1954 Clayton Lecture I said, "The limiting factor in reactor design is the performance of the fuel element and this is likely to be the case for many years to come".

No great improvement in the top temperatures can be expected while we continue to use magnesium alloy canning material. It will be necessary to use either stainless steel, which is an uneconomical absorber of neutrons, or some material having a low neutron cross-section and a high melting point, such as beryllium. But beryllium is an expensive metal and one which is costly and dangerous to handle. It will be necessary to minimize the quantities which are used, and this will mean higher ratings so that the maximum amount of heat is obtained from every fuel element. With high ratings it will be impossible to employ uranium rods of the diameter which are at present used, and even if the fuel elements are made with smaller dimensional cross-sections it is probable that the ratings which are adopted will be so high as to give rise to fuel element centre temperatures which would be dangerous with metallic uranium. It will therefore be necessary to use either a ceramic or a cermet fuel element, and this will additionally be necessary because the steps that will have to be adopted in order to achieve the requisite top temperatures and heat ratings will make the fuel elements far more expensive, and we will require a far higher burn-up of the fissile material than can be achieved with metallic uranium in order to bring their cost per unit of electricity generated down to a reasonable level.

These developments involve an immense amount of difficult research and development work, but it is essential that this work should be carried out expeditiously and successfully. The cost of electricity generated in the nuclear power plants which are under construction is estimated to be between 0·66*d.* and 0·7*d.* per unit. Based on current prices, power will be produced from the best conventional plants which are being built to-day at a cost of only 0·54*d.* per unit, and it is therefore obvious that the present nuclear power plants can only be justified as the foundation for improving nuclear technology. But in calculating the nuclear power cost of 0·66*d.* to 0·7*d.* per unit it has been assumed that these nuclear power plants will be used for base load only and will not be asked to take any share of the peak load. In a conventional power plant only about one-third of the cost of each unit of electricity generated arises from capital charges, the other two-thirds arising from fuel and operational charges. In the nuclear power plants which are at present being built, this proportion is approximately reversed and two-thirds of the cost of each unit of electricity generated arises from capital charges, while only about one-third arises from fuel costs and operating charges. It is therefore obvious that if the present nuclear power plants are asked to take a share of peak load and therefore to work at a lower load factor, they will be placed at a great disadvantage as compared with conventional plants. This was not a matter of great concern at the time when the first plan for nuclear power was issued as a White Paper in 1955. That plan envisaged that by 1965 about 1,800 megawatts of nuclear power plant capacity would be installed. At such a rate of expansion it would be possible to use nuclear power plants on base load for a considerable time. But for various reasons the plan was expanded in 1957 and now envisages an installed nuclear capacity of about 5,000–6,000 megawatts by 1966. At this rate of expansion, nuclear power plants will have to carry a share of peak load by 1971 or 1972. This means that the nuclear power plants which are inquired for in 1966 and ordered in 1967 must have capital costs which are so much reduced as to enable them to compete with conventional power plants when taking a share of the peak load.

Each nuclear power plant which has hitherto been ordered has shown improvement in capital costs as compared with the previous plant, but virtually all this improvement has arisen from straightforward engineering development of the Calder Hall design and scarcely at all from basic scientific or metallurgical improvement. The field for these straightforward engineering developments must be a limited one. Beyond a certain point, it will be impossible to progress unless fuel element technology has been developed to a point which will enable higher top temperatures, higher fuel element ratings and higher fuel element burn-ups to be achieved, and to meet the requirement of the expanded programme this must be done by 1966. In the Axel Johnson Lecture which I gave before the Royal Swedish Academy of Engineering Sciences in 1957 I suggested that if the rate of progress which has been achieved in the nuclear field in the past can be continued, and if the cost of coal continues to rise as it has done, nuclear power should begin to be cheaper than conventional power in the reactors which are commissioned in 1963. But this prediction was based on the rate of expansion of nuclear capacity which was envisaged in the initial White Paper and does not assume the greater fall in load factor which is involved in the expanded programme of 1957. Moreover, there has, I think, been a tendency to assume that these forecasts were predictions of what would happen rather than indications of what should happen. The work described in that paper was done to determine what was a reasonable target for the research and development departments and for the engineers. The results predicted can only be achieved if development continues with the same energy, skill and success in the future as in the past.

It is of vital importance that this rate of progress should be achieved. The engineering technology of the construction of nuclear power plants differs in many important respects from that of the construction of conventional plants, and the engineering capacity of manufacturers in the power plant field is being swung into the manufacture of nuclear plants to an important degree. If, by the 1960's, nuclear plants are not developed with capital costs so low as to enable them to compete with conventional plants when carrying a share of peak loads, then we shall be faced with the alternatives of continuing to build nuclear power plants which will produce more expensive electricity than the conventional power plants that could then be designed, or of swinging the manufacturing technology back from the nuclear to the conventional field.

The expanded nuclear programme of 1957 was adopted for reasons which were considered to be good. It will, however, be a mistake not to realize that, besides involving a far greater rate of capital investment, this larger programme demands a higher rate of scientific and technological development. Progress is necessary not merely in the field of the gas-cooled reactor but also in the development of the fast reactor which, so far as one can see at the moment, is the only device which will enable us successfully to use up the by-product plutonium which is produced in reactors of the Calder Hall type. Moreover, the advance must be made with that same regard to safety in the future which has been achieved in the past; public opinion is so sensitive to nuclear risks that even a minor accident might lead to a setback in the programme which would involve immense difficulties. The problems and the challenge of the next ten years are as great as those of the first ten years. The industrial use of nuclear power cleared its first hurdle in 1956 when Calder Hall went into operation; it must clear its second hurdle with equal success in 1966 when we must be able to build reactors the design of which is so advanced, and the capital cost of which is so low, that they are able to take their share in carrying peak loads of electricity.

CONTROLLED NUCLEAR FUSION REACTIONS

THE presentation of full and authoritative accounts of research on controlled nuclear fusion reactions was a major feature of the second Geneva Conference on the Peaceful Uses of Atomic Energy. This was so partly because of the potential economic importance of the subject, and partly because the conference provided the first opportunity for scientists of all countries to discuss freely their progress to date and their hopes for the future. Many of the principal speakers emphasized that this belated demise of security restrictions is itself a major step forward. Both Britain and the United States formally announced total declassification of all research in this field, and presented data on every aspect of their research programmes.

Approximately one hundred papers were presented, distributed among countries as follows: United States, 66; U.S.S.R., 16; United Kingdom, 9; France, 5; Sweden, 4; and one or two from each of a number of European countries and Japan. While the papers varied considerably in length and significance, these numbers probably reflect at least qualitatively the national research efforts, except perhaps for West Germany, where the work of three research centres was covered by only one paper.

Nearly half the papers were presented orally. The information contained in them was supplemented by an informal session on co-operative processes in plasmas, by films illustrating work in the U.S.S.R. and the United States, by the publication of four volumes[1] of papers from the Russian Academy of Sciences describing work since the inception of fusion research in the Soviet Union, by an authoritative survey of the American programme written by A. S. Bishop[2], and by equipment and data on show at the exhibition. The exhibition displayed the principles of and practical experimentation in fusion research on a scale which, thanks to the American section, must surely be unprecedented for a conference on any scientific subject. Fourteen working experimental set-ups were exhibited, fully instrumented and staffed by research workers. The principles involved, particularly unfamiliar ones such as the rotational transform used in the 'Stellarator', were admirably explained with subsidiary equipment, and a wealth of detail was exposed in static exhibits. Delegates lacked neither stimuli for discussion nor food for thought.

The possibility of producing controlled power from the deuterium – tritium and deuterium – deuterium fusion reactions exists because envisaged conditions in a thermonuclear reactor are calculated to produce more nuclear energy than that used in heating and containing the hot gas. No doubt was cast on this principle in the case of deuterium – tritium reactions. But the energy balance for the deuterium – deuterium reaction is much more marginal, and papers dealing with this problem provided no encouragement that it will be achieved more easily than earlier calculations suggested. A relativistic calculation of the power radiated in harmonics of the electron cyclotron frequency suggested an energy loss hitherto ignored which could in some circumstances be serious. All detailed schemes presented envisaged working only with deuterium – tritium reactions, and on present ideas will require an adequate economic supply of lithium-6.

The problem of generating thermonuclear energy can be tackled in the first instance by using sufficiently rapid compression and high density of deuterium to avoid serious inefficiency from lack of thermal insulation. Academician Artsimovitch reported that experiments showed that deuterium – deuterium reactions, presumed to be thermonuclear, can be produced by heating and compressing deuterium with conventional explosives. Dr. E. Teller canvassed the possibility of underground nuclear explosions, which he suggested could be used for what he aptly called geographical engineering, and to produce a source of geothermal power. In papers dealing with straight unstabilized pinched discharge, it was reported that the energies needed to produce a net output of energy before the magnetic confinement is destroyed by instabilities are calculated to correspond to the explosion of at least ten tons of high explosive. Moreover, experiments suggest that the power used in a straight pinched discharge is limited by evaporation of wall material.

To obtain a more manageable release of energy, much longer time scales are needed; and the majority of papers dealt with the problem of confining hot plasmas with electromagnetic fields, for times long compared to the decay-time of inertial effects and to the growth-time of instabilities. The great majority of these papers were devoted to three principal configurations of magnetic field: the toroidal pinched discharge in which the confining field is primarily the self-magnetic field of the discharge; the Stellarator configuration, where the confining field is generated by external solenoidal windings on a torus or some other form of closed tube; the 'Magnetic Mirror' configuration, where the configuration is that produced in an ordinary straight solenoid, with the field strongly enhanced at the ends of the solenoid to form reflecting zones for the great majority of particles.

Experimental results on the toroidal pinched discharge were reported by groups working at Los Alamos, Livermore, Harwell, Associated Electrical Industries (Aldermaston), Moscow, Saclay and Upsala. Informal discussion suggested that the large apparatus 'ALPHA', built this year at Leningrad, had only just come into operation, and no results from it were presented. The discharge currents reported ranged up to three or four hundred kiloamperes, with rise-times varying from about 10 μsec. in small apparatus to 1·2 msec. in the 1-metre bore ZETA. Results obtained by various groups agreed well on the main points, which are: the pinch effect constricts the current channel away from the wall of the tube; the use of a longitudinal stabilizing field produces a measure of gross stability, but the plasma is not wholly quiescent; the electron temperatures are not more than about $0\cdot5 \times 10^6$ ° K., in spite of the large power input (100 megawatts in ZETA, 900 megawatts in 'Perhapsatron *S*-4') and the high ion energies ($1–5 \times 10^6$ ° K.) measured in ZETA and SCEPTRE; deuterium-deuterium reactions are produced in the plasma, but the energy distribution of the neutrons is anisotropic.

A number of authors dwelt on the cause of the low electron temperature. This is clearly due to a loss of energy from the plasma to the tube walls, but none of a variety of possible energy loss mechanisms has yet been clearly identified. Dr. S. A. Colgate, of Livermore, reported a substantial loss of energy due to electrons of about 5 kV. energy striking the walls; he also reported evidence which demonstrated the importance of gas which continually leaves the walls during the discharge. Straight-tube discharge experiments reported from Los Alamos demonstrated the onset of small-scale instabilities after an initial period of stability. Theoretical papers showed that in the hydromagnetic approximation complete stability could not be predicted for any of the magnetic field configurations so far observed in these pinched discharges. In addition, a number of authors proposed that run-away electrons could generate violent plasma oscillations which could destroy containment. There is also a possibility of the plasma pressure in the discharge becoming too high for containment.

The work on the 'Stellarator' configuration, carried out largely by Prof. L. Spitzer's group at Princeton, has shown that gross containment of a plasma is possible by this means, using a variety of configurations to produce the rotational transform. The containment is limited by a variety of difficulties, the first being contaminants which get into the plasma from the walls. To overcome this, a very high standard of vacuum techniques has been developed, including baked-out stainless steel assemblies, and the 'Divertor', which is a special configuration of magnetic fields which diverts impurities emitted from the walls into cold traps. Secondly, the simplest 'Stellarator' configuration is hydromagnetically unstable, and additional stabilizing windings have been used. Thirdly, ohmic heating by toroidal currents is accompanied by runaway electrons which, as in the pinched discharge, may create violent plasma oscillations which lead to loss of containment. Relevant to this last difficulty, successful experiments on power absorption at the ion cyclotron frequency and other resonances were reported, which show great promise of providing an alternative heating mechanism free from difficulties connected with run-away electrons. Experiments on resonance absorption, in a simple discharge system, were also reported by a group of workers from Kharkov.

Extensive observations of ohmic heating in 'Stellarators' were reported which indicate electron and ion temperatures of about $0\cdot5 \times 10^5$ ° K.; however, because of the above difficulties, the plasma is not yet well confined and reaches the wall in about 10^{-4} sec. Theoretical papers from Princeton dealt fully with the principles of the configuration, the problem of stability and the heating of the plasma by oscillating electromagnetic fields. 'Stellarator' work reported from the U.S.S.R. dealt mainly with unpinched discharges in high magnetic fields; results on stability and temperature were very similar to those reported from Princeton.

Work on the 'Magnetic Mirror' configuration was reported by several American groups and, briefly, by Russian workers from Moscow. The most detailed work on the confining properties was reported in a series of papers from Livermore. Using relatively slowly rising magnetic fields (adiabatic approximation), extensive results have been obtained which demonstrate the confinement, compression and heating of initially injected plasma. The leakage of particles out of the mirrors has been studied in detail, and found to be in rough accord with that expected on binary collision theory. A striking result of this work is that no gross instabilities have yet been encountered; consequently, Dr. R. F. Post and his colleagues have been able to demonstrate a control of the plasma unmatched in other systems. Microwave measurements and the flux and energies of particles escaping through the mirrors indicate densities of up to 10^{14} cm.$^{-3}$, containment times of about 10^{-3} sec., and electron and ion energies of about 10 keV. and 1 keV. respectively. These workers are careful to point out that they have not achieved a sufficiently high ratio of gas pressure to magnetic pressure in sufficiently general circumstances to conclude that large volumes of plasma at useful temperatures and pressures could be stably confined in 'Magnetic Mirror' configurations. Moreover, there is some radial diffusion to the walls which exceeds that calculated for binary collisions.

Due to the leaky nature of the 'mirrors', particularly at low temperatures, the injection of particles or plasma into a 'mirror' machine presents a major problem. Papers from the Oak Ridge group reported considerable progress on injection of D_2^+ ions at high energies. These molecular ions are dissociated in an intense carbon arc inside the mirrors, leading to trapping of deuterons. The ion beams are not yet sufficiently intense to counteract losses due to charge exchange and scattering from neutral atoms and impurities within the mirrors. With sufficiently intense beams, a 'burn-out' of the neutral and impurity atoms should occur. The Russian workers in Moscow propose, in their large OGRA machine, to provide a sufficiently long path for the D_2^+ ions to be dissociated without the use of a carbon arc. Experimental work at the U.S. Naval Research Laboratory demonstrated that rapidly applied mirror fields can provide sufficiently rapid shock heating of a cold plasma to produce considerable trapping and compression to high densities and temperatures. A Los Alamos group reported detailed studies of the neutron emission from such fast-rising mirror fields. Yet another method of heating plasma in the 'mirror' geometry was reported by other groups working at Los Alamos and Livermore, in which radial currents are generated by a central axial electrode. Such currents also produce a rotation of the plasma, as in a Faraday disk. Experimental observation on rotating plasmas were also reported in papers from the University of California Radiation Laboratory at Berkeley.

None of these three principal configurations is obviously hydromagnetically stable, at least in the simplest version; and reports of the experimental observations were complemented by a formidable array of theoretical papers dealing with stability problems. Unfortunately, calculations are straightforward only in the simple hydromagnetic approximation; but the stability may, in fact, depend crucially on such factors as finite Larmor radius, viscosity, anisotropic pressure, toroidal geometry, and other factors which are extremely difficult to include in the already complicated hydromagnetic equations. Other theoretical papers dealt with the run-away electron problem, and the excitation of plasma oscillations by such run-aways.

None of the other confinement schemes reported has been investigated experimentally in detail, and most are in the speculative stage. A machine called the ASTRON, now under construction at Livermore, was discussed by Dr. N. Christofilos; it incorporates a unique feature in that the magnetic configuration is provided both by external coils, and also by a sheath of injected relativistic electrons circulating in the plasma.

A number of papers discussed in detail the practical problems of plasma diagnostics, and while much good work was reported, it was clear that there is still substantial scope for progress in this aspect. A useful contribution was made by a British paper surveying the role of materials in controlled thermonuclear research, describing in particular the concept of 'unipolar' arcs as a process by which impurities are released from the walls.

Thus, the material presented at the Conference showed that in spite of intensive research in a number of countries, there are still many unsolved problems. The three configurations chiefly discussed all have their peculiar difficulties, and neither experimental nor theoretical work is sufficiently far advanced to decide whether these difficulties can be overcome. In no device has there been an unequivocable demonstration of a controlled thermonuclear reaction regardless of energy balance considerations, although according to Academician Artsimovitch "the question of whether a given neutron belongs to the noble race of descendants of thermonuclear reactions or whether it is the dubious offspring of the shady acceleration process, is something that may worry pressmen; but it should not, at the present stage in the development of our problem, ruffle the composure of the specialists".

The emphasis at the Conference was on basic research in plasma physics, and after the Conference most delegates appeared to agree that this will be the most fruitful type of research which can be done in this field for a number of years. R. S. PEASE

AIR SHOWERS OF SIZE GREATER THAN 10^5 PARTICLES*

(3) COMPARISON BETWEEN THE RESPONSE OF GEIGER COUNTERS AND SCINTILLATION COUNTERS

By M. H. BRENNAN†, DR. D. D. MILLAR, M. H. RATHGEBER and C. S. WALLACE

The F.B.S. Falkiner Nuclear Research and Adolph Basser Computing Laboratories,
School of Physics‡, University of Sydney

EXPERIMENTAL investigations of the extensive air showers of cosmic rays have been made by several groups in which scintillation counters or Geiger counters are used for determining the local density of shower particles at several points in a horizontal plane. From these data the shower size and position of the core of the shower may be determined on the basis of an assumed, or experimentally determined, shower structure function, which relates the particle density to the distance from the core. A Geiger counter records only the traversal of one or more ionizing particles through it, while the scintillation counter provides a pulse-height which is proportional to the total ionization produced by all the particles traversing it. The number of particles is then generally taken as the total pulse-height divided by some average pulse-height obtained from the traversal of the scintillator by single cosmic-ray μ-mesons. The estimates of particle density obtained from different types of detector may therefore differ. The present observations were made with the Sydney air shower array in order to compare the response of a tray of Geiger counters with that of the scintillation counters of which the array is comprised.

The array of scintillation counters and the method whereby the size of shower and location of core are obtained for each shower has been described[1]. Also included in the array was a tray of forty Geiger counters of total area 0·382 m.^{2} (see Fig. 1, ref. 1). For each shower detected by the array the number of Geiger counters struck was also recorded on the same punched paper tape which carried the scintillation counter pulse-heights. The number of Geiger counters struck in each shower was then correlated with the density of scintillator particles at the location of the Geiger tray. This density was predicted by the electronic computer SILLIAC, from the computed size of the shower and the location of the shower core. The density of particles predicted at a point occupied by a scintillator has already been compared with the observed scintillator particle density[1] and shows good agreement between prediction and observation.

The predicted density of scintillator particles has been compared with the density of particles as it would be measured by Geiger counters by assuming that $\rho_g = \beta\rho_s$, where ρ_g is the Geiger particle density and ρ_s is the predicted scintillator particle density. It remains to find the best value of β to fit the observations.

The probability that out of forty Geiger counters, each of area a, exactly n Geiger counters will be struck by an incident density of ρ_g particles is assumed to be binomial and is then given by:

$$P(n) = \frac{40\,!}{n\,!\,(40-n)\,!}\{1 - \exp(-\beta\rho_s a)\}^n \times \{\exp(-\beta\rho_s a)\}^{40-n}$$

The total number of showers recorded with the Geiger tray in use was 1,009. For each shower, ρ_s was computed from the location of the core and shower size, and the expression:

$$-n \log_e \{1 - \exp(-\beta\rho_s a)\} + (40 - n)\beta\rho_s a$$

computed for each of forty values of β, ranging, in steps of 0·03, from 0·1 to 1·27.

For each value of β, a total was formed by summing these expressions for all showers. These forty totals then represent the β-dependent parts of minus the logarithm of the probability that the results observed could have been caused by the corresponding value of β. We therefore take that value of β having the lowest total to be the best estimate of the Geiger to scintillator ratio. This value is 0·67. The relative likelihood of the next lowest value tried, 0·64, was exp (− 12), and that of the next highest value, 0·70, was exp (− 2). The value 0·73 had a relative probability of exp (− 21). It therefore seems reasonable to ascribe to β the value 0·68 ± 0·02.

This value has been used in order to transform the shower sizes determined by the analysis of our scintillator observations into the equivalent sizes which would be obtained by using an array of Geiger counters. Because of the form of the shower structure function, this consists of multiplication of our computed number of particles in the shower by the factor 0·68.

While the result of this analysis gives us a method of comparing the estimates of shower sizes obtained by different types of detectors, it is quite possible that the ratio of Geiger particle density to scintillator particle density may vary with distance from the shower core, in which case the shower structure function as measured by a scintillator array would differ from that measured by a Geiger array, and the use of the value of β obtained by the method described above to convert shower sizes into 'Geiger particle' sizes would no longer be strictly valid.

If β is a function of the radial distance r, then the value of β we have obtained is a weighted mean value, the weights being proportional to the frequency of occurrence of showers at a particular distance and to the density of particles $\rho(r)$ at this distance. A correct size conversion factor should have the form:

$$\frac{N_g}{N_s} = \frac{\int r\beta(r)\rho_s(r)\mathrm{d}r}{\int r\rho_s(r)\mathrm{d}r}$$

The data are at present being analysed for evidence of a variation of β with distance from the shower core. The present indications are that such variation as may exist will have an insignificant effect upon the shower size spectrum already quoted[1].

FURTHER OBSERVATIONS ON TUMOUR-ENHANCING FACTORS: THEIR BEARING ON THE IMMUNOLOGICAL THEORY OF CANCER

By Prof. H. N. GREEN and R. WILSON

Department o Experimental Pathology and Cancer Research, University of Leeds,
and Cancer Research Unit, University of Sheffield

WE[1] have described the enhancement of transplanted homologous tumour growth by pretreatment with tumour saline-soluble protein, a lipoprotein fraction, a refined pure phospholipid fraction or crude phospholipid derived from frozen tumour. Since that time the work has extended and the now voluminous details have been incorporated in a thesis by one of us (R. W.). The consistency of the results is a striking feature of this work. The tumours mainly used were the Sheffield *Rd*/3 sarcoma, the Walker carcinoma of the rat and the Crocker sarcoma of the mouse.

Frozen tumour (0° C. for 14 days) yields more active extracts than fresh. Crude phospholipid is only active when derived from frozen tissue. The crude substance from fresh tumour becomes highly enhancing after final precipitation of the tumour-enhancing factor with acetone and magnesium ions, but the saline-soluble fraction is active when prepared from fresh homogenized tissue.

The following facts are all relevant to the possible mode of action of enhancing factor.

The enhanced tumour retains its property indefinitely in the same strain of animal. It is a permanent inheritable property.

Enhancement by enhancing factor from a similar tumour is maximal or nearly so; further enhancement by a second treatment is not obtained. Enhanced tumour contains more enhancing factor than unenhanced. When a tumour after long transplantation has achieved its maximal growth-rate, enhancing factor is devoid of effect. This accounts for failure to obtain enhancement in Sheffield in the *Rd*/3 sarcoma which has been propagated in the same strain for many years and for success with a recently induced slower-growing sarcoma.

Enhancement is thus a form of induced rapid 'adaptation' to the immune resistance caused by strain differences in the host. A tumour springing from an inbred strain does not respond to enhancing factor treatment in this strain.

The enhanced tumour has the remarkable capacity of inducing a similar permanent property in a normal tumour inoculated in the same animal. When such tumours are transplanted separately in opposite flanks the normal grows out at the enhanced rate. A typical experiment is shown in Table 1. It is not even essential that the enhanced tumour be still present, for if grown in the tail to a moderate size, followed by removal of the tail, a normal tumour afterwards transplanted grows at the fully enhanced rate. This again is a permanent reproducible property.

Table 1. GROWTH OF BILATERALLY TRANSPLANTED ENHANCED AND NORMAL *Rd*/3 SARCOMA AND OF A TUMOUR MIXTURE IN RATS (GROUPS OF 6)

Transplant	Original tumour wt./100 gm. carcass (12 days)	Re-transplant tumour wt./100 gm. carcass (12 days)
Bilateral:		
Enhanced tumour	14·1 ± 1·6	14·6 ± 1·4
Normal tumour	13·6 ± 0·6	14·9 ± 1·5
Mixture—half and half (w/w)	4·8 ± 0·9	3·8 ± 1·6
Enhanced:		
Tumour alone	14·0 ± 1·3	12·9 ± 0·9
Normal:		
Tumour alone	5·0 ± 1·0	5·9 ± 1·0

A perhaps even more surprising effect is that when enhanced and normal tumour are mixed before inoculation the tumour grows at a normal or often subnormal rate (Table 1). This reversal is again a permanent and reproducible change. Some effect is observed when the normal forms 10 per cent only of the mixture and at the 30 per cent level the effect is maximal.

Soluble protein or phospholipid from normal tissues (for example, liver, kidney, spleen) or from another tumour type (for example, Walker) also show enhancing factor activity, but it is roughly half that of enhancing factor derived from the tumour under test. Even tumour of a different species contains enhancing factor; mouse Crocker tumour phospholipid, for example, was as active on a rat sarcoma as phospholipid from normal rat tissue. Hen egg phospholipid was, however, not enhancing, so that activity may be dependent on a fairly close species relationship. There is, however, a high degree of tissue specificity in enhancing factor, for when derived from a similar tumour it is at least twice as active as that from another tissue.

Table 2. EFFECT OF 1-2-5-6-DIBENZANTHRACENE (INTRAPERITONEALLY) AND YEAST ZYMOSAN (INTRAVENOUSLY) ON THE GROWTH OF ENHANCED AND NORMAL *Rd*/3 SARCOMA

Amount	Type of sarcoma	No. rats	Tumour wt./100 gm. carcass at 12 days
20 mgm. DBA/kgm. body wt.	Enhanced	6	17·2 ± 1·3
		2	11·9 ± 1·0
		2	2·2 ± 0·2
	Normal	1	4·2
		3	2·0 ± 0·4
		4	0·6 ± 0·3
			Regressing
		2	Complete regression
Nil	Enhanced	10	19·5 (± 3·1)
	Normal	10	9·0 (± 1·6)
4 × 20 mgm. kgm./body wt. zymosan	Enhanced	4	11·7 ± 2·1
	Normal	3	1·0 ± 1·3
	Normal	1	Complete regression
Nil	Enhanced	8	18·3 ± 1·7
	Normal	8	8·8 ± 1·0

The action of tumour inhibitors provides another clue to the nature of enhancement. The enhanced tumour is much more resistant to the carcinogen dibenzanthracene, and to repeated small doses of yeast zymosan both of which powerfully inhibit the growth of the normal tumour (see Table 2). Such treatments augment the resistance of the host to the tumour, and enhancing factor must therefore either greatly lower the general resistance or protect the tumour from its effects. Among many points in favour of the latter view the fact that enhancement continues in the untreated host is decisive.

The chemistry of enhancing factor, more particularly of the active phosphatides which are more readily obtainable in bulk than the lipo-proteins, has been intensively studied. Why is crude phospholipid from non-frozen tissue inactive and even inhibits tumours? Freezing destroys or inactivates the factor, which can be removed from crude lipid by a final treatment with acetone and magnesium ions. There is some evidence that this inhibitory factor is an unsaturated fatty acid, which is gradually inactivated (? saturated) in the frozen state.

A 'cephalin' tumour fraction containing all the amino-N-phosphatides as obtained by fractionation of refined phospholipid on a silicic acid column and a related fraction, but devoid of acetyl phosphatides, as obtained by chemical extraction, has full enhancing activity when mixed with cholesterol but none without. The choline-containing lecithin fraction, though it contains no cholesterol, acts like it in this respect. The sub-fractions of tumour 'cephalin'[2], phosphatidyl ethanolamine, phosphatidyl serine and inositol phosphatide were inactive, as was also crude acetal phosphatide[3]. The silicic acid column choline-containing fraction is not only non-enhancing with or without cholesterol but is sometimes strongly inhibitory. Pure lecithin[4] and crude sphingomyelin[5] were both inactive. With J. W. Westrop[6] it was shown that the powerful hæmagglutinating effect of tumour and normal tissue 'cephalin' can be induced by a lipid–lipid interaction of ethanolamine phosphatide and a phosphatidic acid. Agglutination is chemically closely associated with enhancing phosphatide, and it is quite possible that a similar lipid–lipid interaction is involved in enhancement.

The tumour lipo-protein fraction (50 per cent ethanol-soluble fraction of the soluble proteins) contains not only all the enhancing activity but also strong hæmolytic and, in the presence of free –SH groups, agglutinating activities. It comprises only 2–4 per cent (dry weight) of the tumour protein and contains about 10 per cent lipid and probably nucleic acid.

It appears to account for the total enhancing activity of the tumour. In terms of phosphatide it is estimated to be much more potent than tumour 'cephalin'.

There is no doubt that enhancement is an immunological process. It is a hereditable property of the cell, which can be induced systemically in a remote unenhanced tumour. Serum globulin from rats bearing an enhanced tumour has slight, but definite, enhancing power. Enhancement fails to occur when concurrent cortisone treatment is given. One argument against any pharmacological effect is that admixture of active phosphatide with a tumour inoculum results in no, or very little, enhancement. Another is that tumours indigenous to an inbred strain cannot be enhanced by treatment. The fact that enhancement is strictly strain-specific is crucial. The Crocker tumour, capable of growth in several strains of mice, when enhanced in one strain, shows no enhancement in another untreated strain unless previous enhancing factor treatment has been given. The enhanced tumour, even after growing for many generations in a non-enhanced strain, retains full enhancement in the strain in which it was enhanced. In a mouse strain (*C 57B*) normally completely resistant to the Crocker tumour, prior treatment with enhancing factor enabled it to grow readily to a lethal size. Absolute resistance to strain-specific breast tumours can be broken down and prolonged growth obtained. The fact that both active tumour phosphatides and lipo-proteins induce antibodies reacting *in vitro* with the phosphatide underlines the immunological nature of the effect.

Tissue phosphatide or lipo-protein fractions do not induce the characteristic tissue response, including a plasma cell increase in the spleen, seen when homologous living cells are injected[7]. It seems likely that pre-treatment with enhancing factor provides primary sensitizing antigen, and a rapid outflow of lipo-protein antibody is stimulated by the secondary challenge with living tumour cells. It was postulated[1] that such an antibody may be an incomplete blocking antibody, the primary antigens being modified by freezing or the extraction processes in which, as has been suggested[8], destruction of nucleoprotein antigens leaves some cytoplasmic antigens intact.

The fact that a new and permanent strain of cells appears is all-important and it would seem that either adaptation and/or selection is involved. In favour of selection is the speed of the effect, for it was found both by direct weighing and by re-transplantation that permanent enhancement occurs within 48 hours. It seems unlikely that adaptation, for example, by iso-antigenic deletion resulting in a strain identical to the host could occur in so short a time. We have some evidence that the enhanced tumour contains more enhancing factor rather than less. There is also evidence[9] that widely transplantable tumours contain more isoantigen than do more restricted tumours.

The evidence favours selection of more rapidly growing cells by a lipo-protein antibody. Why is such an effect strain-specific ? In the case of the phosphatides it is likely that after injection they form a lipo- (nucleo-?) protein complex, which behaves as an auto-antigen. When challenged with living tumour cells the host, already sensitized to tumour lipid, could rapidly produce antibody to tumour lipo-protein containing the same haptene. Since it is the 'cephalin' phosphatides that enhance, the antibody would be a 'cephalin'-protein complex specific for protein (iso-antigen) of that strain. If a different strain is inoculated with the enhanced tumour, a new iso-antigenic relationship is established and the normal immune response occurs. Enhanced cells are presumably selected because they contain more surface antigen, enabling them to attract more blocking antibody and thus prevent nuclear iso-antibody reaching its target. This must also hinder the release of nuclear iso-antigen, for the enhanced tumours elicit a weaker immune response from the host, as judged by the size and plasma cell content of the spleen, than the unenhanced. It seems feasible then that a non-lethal lipo-protein antibody blocks both the extracellular release of nuclear iso-antigen and access of nuclear iso-antibody to the nucleus. In order to account for strain specificity the responsible surface antigen must be structurally related to nuclear iso-antigen, possibly having the same protein or nucleoprotein combined with 'cephalin' phosphatide. Enhancement would on this basis be a method of making the tumour nuclear iso-antigens immunologically ineffective by previous immunization with a related lipo-protein cytoplasmic antigen. Cells thus selected with a greater surface concentration of the 'cephalin'-protein complex would be automatically protected from the normal nuclear immune mechanism and thus enhancement would be permanent, but only in the strain in which enhancement was originally induced. Under such conditions blocking antibody would continue to be elicited by excess surface antigens. Remote enhancement occurs even after removal of the enhanced tumour, for so long as effective antibody is in circulation enhancement will occur.

Enhancement can be regarded as a state of greater malignancy corresponding to the normal but slower progression of the transplanted tumour toward greater freedom from immune attack, when it exists. If natural selection is occurring, those cells containing more enhancing antigen appear gradually to predominate. This gradualness suggests that 'enhanced' tumour cells are held in check by less rapidly growing cells just as seems to occur in the experiments cited. The mechanism of this remarkable check is not clear. It may be due to a more powerful lethal antibody response to unenhanced cells overwhelming locally enhanced cells, though admixture with cells of normal organs is without effect. It may be a manifestation of an auto-regulatory control, in which surface antigens from less malignant cells in close contact with more malignant cells restrain growth by passage into or on to such cells and thus transforming them. However, the restraint in a normal mixed tumour cell population gradually weakens, as usually a more malignant cell race gradually preponderates. Slow progression to increasing autonomy is a feature of malignancy. Even the increased rate of cell proliferation in the early stages of carcinogenesis may prove to be the first step in enhancement towards neoplasia.

In this connexion it is of interest that certain substituted carcinogens (for example, the 9-amino, 9-nitro and 9-*iso*cyanate derivatives of 1-2-5-6 dibenzanthracene), instead of being tumour inhibiting like the parent compounds, actually accelerate growth. Even a normally powerful non-carcinogenic tumour inhibitor (for example 11–12 benzfluoranthene) may, in the presence of a high natural immunity, abrogate this immunity[10]. Is it possible that the antigenic nature of the protein-bound substituted compound is sufficiently different from that of the parent carcinogen as to elicit an antibody blocking, instead of reinforcing, the action of tumour-induced antibody ? There is an indication here not only that carcinogenesis involves an immune process but that its mechanism may even be related to that of tumour enhancement.

What bearing have these findings on the immunological theory of cancer[7,11–17] ? This ascribes neoplastic change to a loss of immunological identity in the cell. The theory embraces the idea that cytoplasmic tissue-specific antigens (lipo-protein complexes), rather than nuclear iso-antigens, are involved primarily. A clue to the nature of such tissue-specific antigens is provided in our enhancing experiments. Although enhancement is obtained with normal tissue or tumour phosphatide from another species (mouse to rat), the effect is about doubled by using isologous tumour phosphatides which confer greater tissue specificity on the antigenic lipo-protein and thus appear to stimulate a greater output of tumour-specific antibody by living tumour. So cytoplasmic 'cephalin' seems to show definite tissue-specificity.

Both certain choline-containing phosphatides and some factor(s) in tumour soluble protein fractions stimulate resistance to tumour growth. This increased immunity could be due to antibodies to cytoplasmic lipo-proteins which do not block the effect of the nuclear iso-antibody but reinforce it. A very active factor possibly of this nature is precipitated from the soluble proteins by glutathione treatment. This treatment also preserves the strong hæmagglutinating action of the extract, which otherwise rapidly disappears. The tissue 'cephalin' phosphatides are exceedingly surface active and produce hæmagglutination at very high dilution[6,7]. The choline-containing phosphatides have no such action and some fractions inhibit the 'cephalin' effect. Now the soluble proteins from a wide range of tumours strongly agglutinate red and other cells, whereas very few normal tissues do and then more feebly. Moreover, mouse skin acquired this property during the course of chemical carcinogenesis. The agglutinating factor in tumours is found in the lipo-protein fraction containing the enhancing factor, and free sulphydryl groups are important in both actions. These and other facts[17] suggest that 'cephalin-containing' lipo-proteins are particularly prominent in malignant tumours and reflect a change starting early in carcinogenesis. There is some chemical evidence of this, for in a rat hepatoma there was[18] a significant increase in 'cephalin' mainly in the cytoplasm, with a decrease in lecithin, and in a mouse breast tumour more 'cephalin' and less lecithin than in resting or pregnancy-stimulated breast tissue were found[19].

The different growth potentialities of the cells in one tumour may reflect differences in the amount of 'cephalin'-protein complexes at the cell surface. There is firm evidence that progressive deficiency in a soluble protein fraction occurs during carcinogenesis and some evidence that a lipo-protein is involved[17]. We would therefore speculate that the missing proteins are of a type bound to choline-containing phosphatides and that their loss is accompanied by a relative or absolute increase in those bound to 'cephalin' phosphatide.

If lipo-protein imbalance is related to malignancy then we have to consider how the change is initially brought about. We have shown[7,11–17] how malignant properties could be accounted for by loss of tissue-specific antigen(s). The inducing mechanisms, according to theory, include an immune attack of the host provoked by a chemical- or radiation-modified tissue-specific protein complex and nutritional competition or deficiency due to the action of hormones, viruses or the conditions of tissue culture. It was postulated that in chemical carcinogenesis the initial change is the formation of a tissue-specific auto-antigen and this may prove to be true of many forms of tumour induction. The well-known fact that chemical carcinogenesis is inhibited in the absence of free SH groups in the tissue may be linked to a similar relationship to antigenic and hæmagglutinating activity in tissue lipo-proteins. Other, possibly lethal, immune reactions may occur as the result of non-specific binding or alteration of nuclear antigens. Antibodies to cytoplasmic lipo-protein antigens are less lethal and thus may be able to induce a progressive adaptive loss of such antigens. On the basis of current work, loss of a membranous lipo-protein complex containing a phosphatide of the lecithin type can be envisaged. This is obviously speculative but any clue to the site of specific binding by a carcinogen has value. It embraces the idea that the tissue-specific antigens concerned are 'lecithin' (choline-containing) protein complexes. It is significant that chronic choline deficiency itself[20–23] will induce cancers of the liver and other sites, and tumour formation due to this[24] or to butter yellow feeding is prevented by riboflavin. This suggests that a choline phosphatide is involved, particularly as dietary ethanolamine also strongly inhibits azo dye carcinogenesis[25], and dietary ethionine induces liver tumours[26], possibly, we suggest, by blocking choline synthesis. Moreover, liver tumours are unable to condense formate with glycine and then decarboxylate serine[27], which may be another pointer to a disturbed phosphatide balance. Another possibly relevant point is that admixed lecithin in excess has an anti-carcinogenic effect[28], which could be due to deviation of the carcinogen to a non-specific lecithin protein complex. It was suggested[13,14] that tumour induction by hormonal excess or tumour promotion by substances like croton oil, 'Tween 60' or certain viruses could be a result of nutritional deficiency. Rapid cell proliferation is accompanied by a big increase in phospholipid turnover and its long perpetuation in a damaged tissue could theoretically lead to local deficiency in an essential factor (for example choline) in phosphatide synthesis. Similar events could account for malignant transformation in tissue culture. A direct tumour virus like the Rous is rich in phospholipid, and a close chemical affinity of virus to cytoplasmic lipo-protein might enable it to replace competitively a tissue-specific substance. Many speculations on these lines could be made and are useful if only to attract attention to the possible role of phosphatides in carcinogenesis. Despite their surface active properties and the fact that lipo-protein forms a basic part of normal cell membranes, they are almost neglected in the cancer problem.

We have reasoned that tumour enhancement is made possible by an altered chemical structure of the cell membrane peculiar to cancer. If such an alteration exists, it presumably begins early in carcinogenesis, with a progressive loss of certain choline-containing lipo-proteins until the cell identity is sufficiently altered to enable it to evade homœostatic growth controls. Progressive adaptation results in all the carcinogen-induced auto-antigen being lost from the cell; the cancer cell therefore elicits no immune response from the host, and an immune reaction, if any occurs, is one of the tumour to the host[12]. We have discussed[7,11–17] how lack of tissue-specific antigen(s) could account for the anaplasia, invasiveness and rapid growth of the cancer cell. There are several factors involved here, but, if the concept of Weiss[29] is valid that diffusible substances from the mass restrain the growth of similar cells, then tissue-specific substances must be the receptors for these auto-regulatory as well as the endocrine hormones. Possibly organized growth is controlled by a process which on further analysis will be explicable in immunological terms.

The suggested chemical alteration could also account for the decrease in basic proteins[30] in the cancer cell, and the fact that the specific azo dye binding is chiefly to protein of similar type[31]. The present work suggests that there is an alteration in the lipo-protein orientation of the membrane of the cancer cell. If this involves a deficiency of lecithin and an excess of 'cephalin' in certain lipo-protein complexes, it could account for lack of adhesiveness and contact inhibition[32,33]; for an increased negative surface change[34,35], due to a greater content of the more acid and a smaller content of the more basic phosphatides, could account for the greater repulsion of cancer cells one from another.

The work on enhancement, as well as many other lines, stemmed from considerations of the immunological theory. It strongly suggests that lipo-proteins are important cytoplasmic antigens and indicates that certain proteins of this class are deficient in the cancer cell. However debatable many of the present ideas may be they all point to some abnormality in phosphatide configuration as being a feature, possibly the dominant one, of neoplasia.

OBITUARIES

Prof. F. O. Lawrence

The recent death of Prof. Ernest Lawrence of the University of California, Berkeley, brought to a close the active career of one of the greatest figures in the world of science. Prof. Lawrence had contributed to modern physics a tremendous amount of new knowledge and had advanced its frontiers at an unprecedented rate. This rapid extension was no accident, for he was abounding in ideas and the energy and drive needed to overcome the many obstacles in the way of progress. His enthusiasm, skill and originality were each and all of the highest category.

Yet it is interesting to note that physics came near to losing its great exponent. Many fond memories come to my mind from the period of nearly two years that I worked with him in the Radiation Laboratory, and I recall the surprise that I felt when he told me how as a young research student at Yale he had doubts as to his capacity for original work. The doubts were overcome when the then grand old man of American physics, Michelson, visited the laboratory. Michelson did not try to hide his own ignorance of the ideas involved in Lawrence's studies. In turn Lawrence was inspired to stay in the field to which he was soon to contribute on a vast scale. Lawrence laughingly remarked that if one could reach eminence without knowing everything, then perhaps he himself was not so ignorant as he had imagined.

At twenty-nine years of age he became the youngest full professor at Berkeley and director of the Radiation Laboratory. As such he stood in the forefront of nuclear physics for some thirty years. Like Michelson, he never shirked placing himself in the position of a learner, and the many still younger men who served with him had great pleasure in telling him of their successes or failures. His interest in their work was complete, and unstintingly he contributed his own ideas to advance their studies. It is easy to appreciate how he acquired the gratitude and affection of a long line of distinguished scientists who studied with him. The laboratory on 'The Hill' became a veritable Mecca to keen physicists and a succession of Commonwealth Fellows and others became part of the organization which was so peculiarly his own and which was so well adapted to prosecuting the most advanced studies in perhaps the most difficult field of modern science.

The cyclotron is inevitably linked with Lawrence's name, and many institutions are deeply in his debt for the unfailing assistance that he gave in their efforts to equip themselves with one of his machines. Yet it was but one of the many amazing tools fashioned by Lawrence and his team and brought to bear on the problem of the nucleus. Lawrence was a remarkably inspiring teacher, one who in a few words could throw light on a whole field. Much of this ability came from his own deep insight, which allowed him to create for himself 'models' serving a similar purpose to, say, Bohr's model of the atom. Yet he was at home in the company of the most erudite theorists, and had little difficulty in discussing with them the most advanced theories. He was always the inspiring leader—the only essential was some sign in the young researcher of at least a pale reflexion of his own enthusiasm for his favourite subject. Young scientists came to him eagerly and in his own words he "found the genius of men spread rather uniformly over the entire globe". Many later put his methods into practice in their own lands, and so his gifts were multiplied and are still being multiplied.

It is difficult even to enumerate the many discoveries linked with Lawrence and his Laboratory. A host of new radioisotopes were investigated, among them tritium, radiocarbon, uranium-233 and plutonium. Indeed, twelve synthetic elements like plutonium resulted from work at Berkeley. The first laboratory generation of mesons and anti-particles took place there.

Much of his work is of immediate moment to the well-being of mankind. Radioactive tracers and neutrons were applied in biology and medicine, he and his brother John taking the role of pioneers. More directly still he gave of his best in the Second World War when he pushed to a successful conclusion the Calutron project, something which perhaps none but he might have believed possible. He saw the nuclear power age as one which would free miners and others from their toil for coal. Always he sought to raise the standards of living for all. On an international scale he served with the Stassen Committee, and he was at Geneva working towards agreement on the detection of nuclear explosions when illness overtook him.

He lived his life at a tremendous pace and to one who gave all there rightly came many high honours. He was a Nobel laureate, he held the Comstock Prize of the National Academy of Sciences, the Medal for Merit of the United States Government, the American Cancer Society Medal, the Enrico Fermi Medal of the Atomic Energy Commission, the Faraday Medal of the Institution of Electrical Engineers, the Hughes Medal of the Royal Society and the Duddell Medal of the Physical Society. He was an honorary doctor of many universities, including Yale, Princeton, Harvard, Michigan, McGill, British Columbia, Glasgow, and an honorary Fellow or member of societies including the Academy of Science of the U.S.S.R., the Indian Academy of Sciences, the Royal Swedish Academy of Science, the Royal Irish Academy of Sciences, the Royal Society of Edinburgh.

Ernest Lawrence is one of those whose loss is grievous but relieved by the fact that his inspiration lives after him in the memories and works of the many so deeply in his debt. S. C. Curran

Prof. Maurice Caullery, For.Mem.R.S.

Maurice Caullery, honorary professor at the Sorbonne, where he occupied during thirty years the "Chaire d'évolution des êtres organisés", died on July 15 at the age of ninety.

The eminent scientist, to whom zoology owes so many contributions, had been a student at the École Normale Supérieure, where he was a pupil of Alfred Giard. His thesis dealt with the histological phenomena accompanying the seasonal regression and development of Synascidia, and led to the conclusions that the tissues of various organs (nervous system, peribranchial cavity) are ectodermal in the oozoids, whereas, in the blastozoid, they originate from the internal vesicle of the bud, and thus, in the last analysis, from an endodermal tissue. The very same organ might thus be derived from two different 'feuillets'. This unexpected conclusion was the starting point of a comparative study of budding in various Synascidia, and, in particular, in the Didemnidae, where the essential role of the epicardic tube in blastogenesis was discovered.

The Microniscidae were known as parasites of planktonic copepods. Caullery succeeded in demonstrating that they are an intermediate phase between the epicaridic and the cryptoniscian larvæ (epicarids are isopods parasitic on other crustaceans). The study—with Félix Mesnil, who became his brother-in-law—of the cryptoniscian *Hemioniscus balani* revealed the existence of a protandric hermaphrodism. It turned out that this was a general feature of the group : all the cryptoniscians are first males, then females. Caullery and Mesnil also discovered and described a parasite of annelids, *Xenocoeloma brumpti*. The central cavity of this copepod is covered by the peritoneal endothelium of the host, an extreme case of parasitic degeneration.

A number of wandering annelids were known to undergo metamorphosis at the time of sexual maturation, and the altered 'epigamic' worm disseminates the sexual elements. The study of *Dodecaceria concharum* revealed that epigamy also occurs in tubicolous annelids. The discovery by Caullery and Mesnil originated in numerous investigations which revealed unexpected traits in the life-cycle of polychæte worms.

These two French zoologists disclosed the entire life-cycle of orthonectids. The plasmodia of *Rhopalura ophiocomae*, a parasite in *Amphiura squamata*, give rise to germ cells which are the origin of the males and females. These escape from their host ; copulation and fecundation take place, and ciliated larvæ are produced which, when freed, infect a new *Amphiura* and give rise to plasmodia, thus initiating a new cycle.

The invertebrates of the French coast of the English Channel are rich in parasites and especially in parasitic Protozoa. Caullery and Mesnil discovered a new gregarine, *Gonospora longissima*, which provided the first example of schizogonic reproduction in the group. Moreover, it was found that the various phases of the life-cycle of the parasite are controlled by the phases of the life-cycle of the host. This was perhaps, in 1898, the first example of such a type of interaction.

The study of the actinomyxidium *Sphaeractinomyxon* revealed the existence of a new type of sexual process and was the first example of sexuality in the *Myxosporidia*. Finally, Caullery and Mesnil studied or discovered a number of Protozoa, such as the *Metchnikovellidae*, parasites of the cytoplasm of gregarines, the *Siedleckia*, parasites in the annelids : and they created the group of Haplosporidia for a number of Sporozoa the relationships of which they were able to establish.

Maurice Caullery never failed to give his own studies their proper place in a great ensemble. Having studied so many parasites, he naturally was led to write a book on parasitism, "Le parasitisme et la symbiose" (Doin, 1923), now translated into English. His lectures on various biological subjects were also published in book form and exemplify his erudition and critical sense : "Les Problèmes de la Sexualité"

(Flammarion, 1918), "Les Problèmes de l'Évolution" (Doin, 1931), "Les Conceptions modernes de l'Hérédité" (Doin, 1935), "Les Progrès récents de l'Embryologie expérimentale" (Doin, 1939), "Organisme et Sexualité" (Doin, 1942).

These books reflect the excellence of his teaching, which influenced numerous young scientists. A number of them have made brilliant careers in experimental biology and embryology and developed schools of their own.

Maurice Caullery was, in 1928, elected to the Paris Academy of Sciences and in 1948 he was elected a foreign member of the Royal Society. He was also associate or corresponding member of numerous other foreign academies.

Up to the time of his death, Maurice Caullery remained physically and intellectually alert, walking every day to the laboratory, continuing to read and to write. In 1945 he became president of the Academy of Sciences, and, in his presidential address, did not hesitate to denounce its ageing and immobilism, fighting with acidity and vigour for a renewal of its organization. A great sense of duty and devotion to science associated with intellectual youth and vitality were among the characteristics of Maurice Caullery. Throughout his long life, he devoted himself to the advancement of biology.

He is survived by Mme. Caullery and their four children and numerous grandchildren.

ANDRÉ LWOFF

NEWS and VIEWS

The American Air Force Lunar Probe

THE American Air Force lunar probe attempt on October 11 failed to achieve the full objective of a circum-lunar orbit, but demonstrated that many of the technical problems of launching and accelerating a three-stage rocket to the necessary speed have been solved. Guidance of the rocket into the correct path and precise control of the final cut-off velocity appeared to have been the chief problems not yet completely mastered. The tracking of the rocket and reception of telemetry signals both in the United Kingdom and at other stations was very successful out to the maximum distance of almost 80,000 miles from the Earth's surface. In the instrument payload of some 40 lb. were included radiation detectors, which confirmed the earlier measurements on *Explorer* IV of the intense radiation belt surrounding the Earth. Preliminary analyses of the results have shown a significant decrease in intensity beyond several Earth radii, and seem to confirm the idea that the radiation is due to the trapping of cosmic particles by the Earth's magnetic field. Temperature and micro-meteorite impact measurements should give valuable data on conditions in regions now explored for the first time. No doubt there are some who will not regret the failure to penetrate the mystery of the Moon's unseen face, but it must be only a matter of time until this is done; meanwhile, the progress already made and the value of the scientific measurements obtained merit warm congratulations to the American scientists concerned.

Racial Problems in Britain

THE Eugenics Society (69 Eccleston Square, London, S.W.1, 1*s*. 6*d*.) has recently issued the first of a new series of broadsheets, which deals with the subject of West Indian immigration into Britain. In the preface, Sir Charles Darwin explains that the aim is "to review the whole position, so that whatever the reader's final conclusions may be, they should at least be based on fact and not on mere emotion". Recent events in Great Britain have made it plain how important this is; but it is also obvious from the paper itself, written by Mr. Colin Bertram, the general secretary of the Eugenics Society, that the separation of facts from opinions concerning the problem of 'race' is a task of the greatest difficulty.

It is unfortunate that the argument of the broadsheet involves a large measure of confusion between the social and the genetic aspects of the subject, and that it takes so much for granted. As it is assumed that "miscegenation runs counter to the great developing pattern of human evolution", the onus of responsibility is placed on the shoulders of those who are willing to allow it to continue in Britain. There is, it is said, "a need to ponder" on this difficult issue, "unless there are evident ultimate genetic advantages in the production of persons more likely to be capable, happy and altruistic in the circumstances of the future", as the offspring of mixed marriages. It is improbable, however, that any precise information can now be produced which would indicate whether these somewhat vague requirements can be met. Until the problems of race relations are stated in clearer terms, from the genetic point of view, it is unlikely that what has been termed the 'art of eugenics' can contribute significantly to their solution.

Waverley Gold Medal Essay Competition

THE Scientific Advisory Board of *Research* has awarded the following prizes in the Waverley Gold Medal essay competition. The Waverley Gold Medal and first prize: Mr. A. J. C. Hall (University of Sydney) and Mr. J. G. Hayes (Royal Melbourne Technical College) for "Coloured Patterns in Glass"; second prize, Mr. T. R. Manley (A. Reyrolle and Co., Ltd., Newcastle upon Tyne) for "The Irradiation of Plastics"; special prize for an author under thirty: Mr. M. D. Lilley (Aplin and Barrett, Ltd., Yeovil) for "Food Preservation with the Antibiotic Nisin"; highly commended: Mr. J. Heywood (Norwood Technical College, London) for "Radio Astronomy—an Aid to Education". The prizes will be presented to the winners on December 15 at 6 p.m. in the lecture hall of the Royal Society of Arts, John Adam Street, London, W.C.2.

Industrial Training Council

THE Industrial Training Council, which consists of representatives of the British Employers' Confederation, the Trades Union Congress, the nationalized industries, Government departments and educational bodies, and recently held its first business meeting, has the primary function of encouraging individual industries to take action to ensure a satisfactory level of industrial training. The point was emphasized that it is only the organizations in the individual industries that have any executive authority. It was decided, as a first step, that the Council should seek factual information from the industries as to their future needs and opportunities for training personnel. The Council agreed that industries should first be encouraged to undertake the assessments—suggested by the Carr Committee—as to their future man-power needs and to compare these with existing facilities for training. It was stressed in particular that there is an urgent need for each industry to make some quantitative assessment to satisfy itself that its training arrangements will be adequate to meet the coming 'bulge' in school leavers. The Council further decided to ask each industry to state in general terms how far, if at all, it has dealt with the main recommendations in the report of the Carr Committee which cover the whole field of training of young workers.

Graduate Training in Chemical Engineering

It has been realized for many years that a student who has obtained a degree in engineering at a university is by no means fully equipped to take his place in an industrial concern, and many large firms have organized training courses of a practical nature which supplement the fundamental and more theoretical knowledge acquired at the university. In chemical engineering, owing to the diversity of subjects dealt with, it is not easy to decide the exact form which such courses should take, and in view of the increasing demand for guidance in this matter, the Education Committee of the Institution of Chemical Engineers, after consultation with the Association of British Chemical Manufacturers and the British Chemical Plant Manufacturers Association, has now published a brief advisory note. In this it is pointed out that it seems desirable for every chemical engineering graduate to have practical training in four main subjects—the design, fabrication, development and operation of process plant. Two years is suggested as the total period of training, but the time allocated to each subject should vary substantially according to the type of work which the trainee is intended to take up. During the training it should be possible to emphasize such subjects as costing, labour management, safety and report writing. A schedule in somewhat greater detail is given. Twenty-seven large organizations are at present operating training schemes which conform with these suggestions and the note should prove very helpful as a guide to firms which are contemplating the introduction of organized postgraduate training into their business.

Building Research

The latest reports of the Building Research Board and of the Director of Building Research of the Department of Scientific and Industrial Research have been published in a booklet entitled "Building Research 1957" (pp. iv+75+16 plates. London: H.M. Stationery Office, 1958. 5*s*. 6*d*. net). These reports are of special topical interest following the recent criticism of the annual report of the Building Research Station by the Select Committee on Estimates in the course of its inquiry into the finances of the Station; the Committee complained that the report was of too general a nature to be of much value to those interested in the work of the Station. Opinions will, no doubt, differ on this point, but all familiar with the building industry will appreciate the difficulties facing the Director in compiling his report.

In order that the Building Research Station should be in a position to view all building problems in their correct perspective, the programme of work undertaken is very broad, ranging from rheology to the packaging of bricks. The Station is, nevertheless, able to make a number of contributions to basic research in several fields. For example, the high-temperature microscope, described in the report for 1956, has been further developed and a new instrument has been constructed which permits observations to be made in special atmospheres at temperatures exceeding 2,000° C. Further contributions have arisen out of the Station's work on lighting and heating, and an investigation of the aircraft-noise nuisance problem has given rise to some basic research on sound propagation in the open air.

Cancer and Mental Health in 1952–53

The Registrar General has recently issued two supplements to his Statistical Review (Supplement on Mental Health for 1952–3. Pp. xi+208. 11*s*. 6*d*. Supplement on Cancer for 1953. Pp. xi+105. 7*s*. 6*d*. London: H.M. Stationery Office, 1958). The cancer volume is a continuation of previous studies, discussing figures obtained from the cancer registration scheme for eight further sites: in women, the corpus uteri and ovary; in men, the testis and penis; and in both sexes, lip, tongue, mouth and pharynx, and the œsophagus. New registration-rates and mortality-rates are presented for each site, and there are figures showing mortality in each year of treatment and the five-year survival-rate in relation to the clinical state of the disease at registration and by method of treatment, and there is a text section commenting briefly on the principal results.

The supplement on mental health is more comprehensive. It gives figures relating to the population of patients in mental hospitals and mental deficiency hospitals, the duration of stay and the incidence of mental disease, as measured by new registrations, among different groups of the population. The figures are divided by age, marital status and occupation. The period considered is too short for significant trends to emerge, but it might be noted that between 1950 and 1953 the median duration of stay for patients discharged from mental hospitals steadily decreased. The incidence of mental disease is particularly high among the single, and in Group V, the lowest group of the Registrar General's classification. Adverse rates of mental disease also seem to be connected with a high standard of education, clerical and domestic work, labouring and branches of the catering industry, but the Registrar General recognizes that in this field it is difficult to disentangle cause and effect and that further ecological studies are required.

The Neolithic Age in Eastern Siberia

The new volume of the *Transactions of the American Philosophical Society* (New Series, 48, Part 2 (1958): "The Neolithic Age in Eastern Siberia". By Henry N. Michael. Pp. 108. Philadelphia: American Philosophical Society, 1958. 2.50 dollars) will be much welcomed by prehistorians. Here in the West it is not too easy to obtain accounts of investigations made in Siberia, especially as many of the articles are written in Russian. Some little while ago there was a short article on "Eskimo Archæology" by H. B. Collins which appeared in the *Proceedings of the American Philosophical Society*. But this only touched on some of the early stone age finds near Lake Baikal and farther to the north. Merhart's well-known work on the Siberian Palæolithic cultures deals, of course, with discoveries of an earlier period. "The Neolithic Age in Eastern Siberia", therefore, fills a yawning gap in our knowledge of the region. The reader will do well to turn to Table 2 on p. 33 and to read the accounts of the finds in the light of the chronological sequence there set out. Not everyone agrees as to the origins of these various cultures. Fundamentally, however, it would seem that a case has been made out for connexions with the west, for example, with such an area as south Russia. Whether the Magdalenians, drifting north and east following the reindeer and retreating before the ameliorating climate of western Europe, ever reached Siberia is very uncertain, though the possibility should not be ruled out. Anyway, there seems to occur a sort of late Palæolithic–Mesolithic complex and this is followed by a transitional (Khina) culture which in turn heralds the early Neolithic industries (Isakovo) with some pottery and polished stone tools. Naturally in such an isolated region local developments occur. There follow the various Neolithic cultures, and after them those of the true Bronze and Iron Ages. Many of the ideas put forward are necessarily tentative, but the volume does bring up to date what is known of the earlier Stone Ages of these remote regions.

New Vaccine for Fowl Typhoid

A NEW immunizing agent for use against fowl typhoid is now available to the poultry industry. Following initial work by Dr. H. Williams Smith, an Animal Health Trust bacteriologist, on the organism causing this costly and highly infectious disease, the Trust has evolved a 'live' vaccine the efficiency of which has been thoroughly tested and proved in a series of field trials carried out in collaboration with the Veterinary Investigation Service of the Ministry of Agriculture. Prepared from a strain of the organism which is less virulent than most, the new vaccine, known as '9 *RS*', is free from the drawbacks associated with the use of earlier 'live' products—the risk of setting up active disease in the field, and the liability to cause reactions inimical to the success of normal blood-testing for both B.W.D. and fowl typhoid itself. It is therefore completely safe, and supplies for home administration are now offered for sale to all poultry-keepers. It is emphasized that the purpose of the vaccine is to prevent fowl typhoid. It is not a cure. As an illustration of its preventive power, it was shown in one trial that, of a group of birds vaccinated with 9 *RS* and later artificially infected with fowl typhoid, only 6 per cent died, whereas a similar group of unvaccinated birds suffered a 70 per cent death-rate. Further information can be obtained from the Animal Health Trust, Biological Products Department, Kennett, Nr. Newmarket, Suffolk.

Sputniks 1 and 2

MUCH of the preliminary orbital data on the first two *Sputniks* obtained by staff of the Smithsonian Astrophysical Observatory up to March 1958 is collected in *Smithsonian Contributions to Astrophysics* (2, No. 10 : Orbital Data and Preliminary Analyses of Satellites 1957 Alpha and 1957 Beta. Compiled by F. L. Whipple, L. G. Boyd, J. A. Hynek and G. F. Schilling. Pp. vii+189–347. Washington, D.C.: Government Printing Office, 1958. 1 dollar). The aim of the compilation is to publicize the orbital information as quickly as possible, and the various items are printed unrevised. The volume is thus a historical record rather than a critical survey, and many of the early orbital determinations, which were inevitably erroneous, are given equal emphasis with later and more accurate computations. This should be borne in mind when reading the volume, the contents of which are rather varied. There are a good deal of orbital information and a useful glossary of astronomical terms. There are lists of the optical observations of the satellites made by 'Moonwatch' teams, and of the daily predictions transmitted by Moscow radio. There are also two papers giving values of upper-atmosphere density deduced from the *Sputnik* observations, and the suggested 'interim standard atmosphere No. 2' has, in fact, successfully fitted the results from later satellites.

Medical Electronics

A RECENT meeting of an interim committee composed of members of the Institution of Electrical Engineers and of the medical profession having a common interest in medical electronics discussed the scope and future activities of the Medical Electronics Discussion Group, which has been set up by the Institution of Electrical Engineers. An organizing committee, responsible for arranging the programme of the Group, was appointed under the chairmanship of Mr. S. J. Emerson. It was decided that the activities of the Group should be centred around advanced electronic techniques applied or related to medical and biological problems, and there will be a programme of informal discussion meetings which will provide a forum for the exchange of information between the two professions on subjects coming within this field.

The first meeting of the Group is to be held at the Institution of Electrical Engineers at 6 p.m. on November 7, when Dr. A. C. Dornhorst (St. Thomas's Hospital Medical School) will speak on "Measurements of Blood Flow in the Human Subject", and Dr. D. A. McDonald (St. Bartholomew's Hospital Medical College) will speak on "Measurement of Pulsatile Blood Flow". A second meeting will be held on November 28 to discuss the problems which are encountered in the field of neurophysiology, when the speakers will be Dr. Warren S. McCulloch (Massachusetts Institute of Technology) and Dr. W. K. Taylor (University College, London). A third meeting in January 1959 will deal with "The Physiologists' Requirements for d.c. Amplifiers". It is proposed to provide an opportunity at each discussion meeting for members to give notice of any problems they have encountered (not necessarily related to the topic discussed at the meeting), in the hope that others present may be able to offer suggestions for their resolution. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

Department of Scientific and Industrial Research, Research Fellowships

THE following fourteen research fellowships have been awarded by the Department of Scientific and Industrial Research for the academic year 1958–59 to young research workers of exceptional promise who, usually, have already received postgraduate training up to the level of a doctorate : C. J. Batty (nuclear physics, Birmingham), L. B. Tarlo (palæontology, British Museum), J. Biggs (chemistry,

Cambridge), Dr. Enid R. C. MacRobbie (biophysics, Cambridge), Dr. C. J. S. M. Simpson (chemistry, Cambridge), A. K. Kent (zoology, Bedford College, London), R. M. E. Sullivan (engineering, King's College, London), Dr. Amy M. Goodall (chemistry, University College, London), G. Culligan (nuclear physics, Liverpool), P. D. Forsyth (nuclear physics, Manchester), F. H. Read (nuclear physics, Manchester), W. R. Phillips (nuclear physics, Oxford), B. Nicholls (chemistry, The Queen's University, Belfast), G. E. Hall (chemistry, Technische Hochschule, Zurich).

Lalor Foundation Grants

The Lalor Foundation has announced the programme of awards for 1959 which it is offering to college and university faculty members for research in the biological sciences. These awards are to be for support of research on the fundamental biochemical and biophysical mechanisms concerned with fertility and reproduction in various forms of life. The objectives are to work for more complete understanding of the basic phenomena involved and ultimately toward better possibilities for biological regulation and control. Grants may range up to 8,000 dollars per year and will be scaled in proportion to the scope and duration of the projects approved. Preference will be given to younger members of university and college staffs with an upper age-limit of forty-five years. The work may be carried out at the applicant's own institution or elsewhere. The Foundation will also grant postdoctorate summer or short-term research awards in the field described on projects which, for example, would be appropriate to the Marine Biological Laboratory at Woods Hole, Mass., or elsewhere. For these awards, the stipends will normally not exceed 900 dollars for a single man or a woman, 1,100 dollars for a married man working at his home institution, and 1,250 dollars for a married man with his principal programme at another institution. Application and inquiries should be directed to the Lalor Foundation, 4400 Lancaster Pike, Wilmington 5, Delaware, and applications must be received by January 15, 1959.

Bedson Club Lectures

The programme of lectures of the Bedson Club, King's College, Newcastle upon Tyne, during 1958–59 will be: October 31, Prof. R. A. Raphael, "The Acetylenic Approach to the Synthesis of Natural Products"; November 21, Prof. H. C. Longuet-Higgins, "Recent Developments in Quantum Chemistry"; January 23, Prof. E. G. Cox, "The Molecular and Crystal Structure of Benzene"; February 20, Dr. R. E. Richards, "Recent Developments in the Chemical Applications of Nuclear Resonance Spectroscopy". The following lecture will be given in association with the Royal Institute of Chemistry: November 7, Dr. J. Harris, "From Barley Corn to Bottle". The following lecture will be given in association with the Society of Chemical Industry: January 16, Dr. E. R. Wilson, "An Industrial Approach to Basic Research: Fabric Substantive Fluorescing Agents". The lectures will be given at 5.30 p.m. in the Chemistry Department.

Announcements

Dr. Harold Moore, director of the British Non-Ferrous Metals Research Association during 1932–44, has been elected an honorary member of the Iron and Steel Institute, of which he has been a member for fifty-seven years; of the twelve living honorary members of the Institute, only one other, Sir William Larke, is British.

Mr. M. G. Morris (Cambridge) has been awarded the first V. H. Blackman Postgraduate Research Studentship, of £500 per annum for three years and tenable at East Malling Research Station, for research in applied entomology.

The annual general meeting of the Association of Clinical Biochemists was held at the Royal College of Surgeons, London, on October 4. The following officers were elected for 1958–59: *President*, Prof. E. J. King; *Chairman*, Dr. A. L. Latner; *Honorary Treasurer*, Dr. J. H. Wilkinson; *Honorary Secretary*, Dr. A. L. Tárnoky, Royal Berkshire Hospital, Reading.

The Education Panel of the Corrosion Group of the Society of Chemical Industry will again award a prize for an essay on corrosion science by a young author, less than twenty-seven years of age by the closing date, March 31, 1959. A length of about 4,000 words is suggested. Further information can be obtained from Corrosion Group Essay Competition, c/o Society of Chemical Industry, 14 Belgrave Square, London, S.W.1.

Full-time and part-time courses in polarography organized by the British Polarographic Research Institute will be available during the session commencing November 1958. Further information can be obtained from the secretary, Mr. W. J. Parker, 55 Oriental Road, Woking, Surrey.

The Northern Branch of Aslib is arranging a symposium on "Practical Aspects of Special Library Work" in Sheffield on November 27 and 28. Further information can be obtained from Miss E. Boddy, The Retreat, Tideswell Lane, Eyam, Nr. Sheffield.

A conference on "Fuel and Power in British Industry" organized by the Manchester Joint Research Council is to be held in the Manchester College of Science and Technology during November 5–7. Sessions will be devoted to resources and utilization of coal and of oil, to nuclear power and to electricity. Further details may be obtained from the Joint Hon. Secretaries, Manchester Joint Research Council, Manchester Chamber of Commerce, P.O. Box 559, Manchester, 2.

The autumn meeting of the Parasitology Group of the Institute of Biology will be held on October 24, in the rooms of the Royal Entomological Society, 41 Queen's Gate, London, S.W.7. The morning session will be devoted to "Chemotherapy of Parasitic Diseases", followed in the afternoon by a discussion of "The Problems of Publication", from the points of view of editor, publisher and contributor. The meeting will be open to non-members. Further details can be obtained from the honorary secretary of the Parasitology Group, Dr. June Mahon, Department of Zoology, Bedford College, Regent's Park, London, N.W.1.

Erratum. In the communication entitled "'Crossing' Paper Electrophoresis for the Detection of Immune Reactions", by Prof. S. Nakamura and T. Ueta, published in *Nature* of September 27, p. 875, in Fig. 1*A* the line labelled *Ab* should be labelled *Ag* and *vice versa*.

CONTEMPORARY PROBLEMS IN MATHEMATICAL TEACHING AND STAFFING

It is now generally recognized that, in the drive to meet the modern needs of Great Britain on the industrial side, many new problems are emerging in relation to the creation of the necessary scientific and technological personnel. Two of these, in particular, arise out of the comparatively recent appreciation of the fact that mathematics has moved into a central position in the study and development both of science and of technology. There is scarcely a sector of these that is not leaning more and more on mathematical techniques. This, therefore, poses a new task to the mathematical profession; and those who are concerned that it should be effectively carried out can see at once the two problems that stand out sharply. One relates to the content and mode of presentation of the subject-matter that must be taught both at school and at university. The other is concerned with the supply of teachers with mathematical qualities adequate to the new tasks that face the profession. It is therefore not at all surprising that at almost every scientific gathering these two issues come up for discussion.

Section A (Mathematics) jointly with Section L (Education) of the British Association meeting in Glasgow devoted the whole morning of September 2 to precisely these questions. Mr. W. J. Langford, president of the Mathematical Association, presented an interesting survey of the history of the movement for reform of mathematical teaching at schools, from the days when "Euclid" constituted the mathematical Bible, to the modern many-sided approach, where it is possible to dip into the calculus at a relatively early stage. Now, however, the problem has sharpened in another way. As the universities strive to carry their final-year students right to the frontiers of knowledge in this rapidly developing field, the schools are expected to keep pace with what must inevitably be a rising standard of entry, unless, indeed, the period of university study is itself correspondingly lengthened; and this is occurring at a time when apparently less than one-third of those engaged in the teaching of mathematics at school have specific qualifications in this subject. Mr. Langford indicated the possibility that in the near future there may be established an institute of mathematics, comparable to the engineering institutes, which might offer a qualification capable of being acquired by teachers of mathematics who have not reached graduate standard, but are willing to improve their knowledge of the subject presumably while still engaged in teaching.

The dangers inherent in the present position were sharply underlined by Prof. L. Rosenhead, who made a searching survey of our present resources in mathematical personnel, in order to examine how far it might be possible by 1970 to attain to double the number of mathematical teachers that were available in 1955, as hoped for in the present plans. Whether it is consciously visualized or not, for this purpose school and university education is a single process, so that in the last resort the problem of the universities and the colleges in this matter of scientific and technological supply is intimately bound up with what happens in the primary schools. In the U.S.S.R. this has long been recognized, and they are now reaping the advantages of planning on an integrated basis. In Britain, teachers of arithmetic at the primary stage have in general no mathematical knowledge; while again, at the later stages, the potential mathematical interest of the children is often destroyed by the inability of the teacher to awaken the interest of the pupil by opening up to view the wider horizons. At the present moment, there is a frantic search for mathematical school teachers. Since quite a large proportion of those who actually teach the subject have almost negligible qualifications in it, already in some girls' schools the teaching of some branches of mathematics has been given up. In such circumstances, deterioration must inevitably set in.

Prof. Rosenhead asserted that over the past twenty years there had been a definite fall in the level of preparedness at university entry, and if university standards are to be maintained, as they must, the proportion of failures is bound to increase. As a temporary measure he suggested an expansion of the present trend towards the grouping of schools on an area basis for such special teaching, and that no one should be allowed to remain in the sixth form for more than two years. Such expedients, of course, clearly do not get down to the root of the matter, which is the simple fact that those who take high mathematical qualifications at the university are now being attracted elsewhere than into the teaching profession. Industry has within the past decade become conscious of the fact that it is able to use highly skilled mathematicians of almost all kinds—both pure and applied, analysts and computing machine programmers—and the nature of the tasks such mathematicians encounter seem to appeal to them more strongly than the work of the teaching profession. Over and above all this, of course, is the hard fact that salaries are higher in industry. It has therefore become the exception rather than the rule to find mathematical students who are keen on teaching as a career. A generation ago the converse was true. It seems to follow that the standard of mathematical qualification within the teaching profession must deteriorate, so that industry itself will finally begin to experience the effect of the shortage which it is itself helping to create. The fact is simply that there is too small an output of mathematicians to meet the prevailing needs, and the particular advantages that industry can offer tend to canalize those who are produced into that field. In such a situation, the decision as to which is the greater social priority is being left to blind economic forces. As both Mr. Langford and Prof. Rosenhead stressed, in present circumstances the coming generation cannot possibly reach a standard of achievement in keeping with its native ability.

Again the content of, and the approach to, mathematical teaching came under very sharp review. Mr. Langford had pinpointed the successive advances that had been made in school teaching since the "Euclidean" days, and the gradual recognition that mathematics is a single co-ordinated subject, where it is possible to introduce such topics as analytical geometry and calculus long before algebra and geometry had been carried to the limits of school achievement.

Prof. H. Levy dealt mainly with the teaching of applied mathematics, at the university-level, to students of various faculties. He pressed the view that diagrams on paper and blackboard should be realistically seen for what they are—simplified physical 'models' in chalk or carbon particles of actual things. Already, even at this stage, irrelevant elements in the medley of events in the real world have been dropped out, and from this rather grotesque model, sticking to an almost flat surface, it becomes relatively easy for the student to make the mental abstractions we call lines, curves and points. Mathematics, he asserted, deals in the first instance only with these abstractions, and in this way the mathematician sets out to develop a logical deductive system in place of the actual physical process that is being studied. The laws of Nature—Newton's laws, for example—are extracted and abstracted from the medley of real objective events 'out there', and enter as mere mathematical assumptions into the logical analysis. It is important for a student, to see this clearly in order to undermine the 'mystique' of a mathematically derived formula, and to underline the fact that its validity finally rests on verification by observation or experiment, and not merely on logic. In all this, imagination plays a very important part. To construct the appropriate 'model' on paper or blackboard, from the physical sequence of events, requires a considerable effort of the imagination; just as the sense of logical conviction itself rests on a mental scrutiny of imagined alternatives at each step of a proof.

From this point of view Prof. Levy sharply criticized the usual sets of examples and exercises in text-books, in which the author himself has already made the principal geometrical abstraction, expressing it through the phrasing of the question, while the dynamical principle that is to be used in the logic is made obvious from the place of the example in the text-book. While not undervaluing that kind of 'drill', he insisted that teaching and learning are simply two aspects of one process in which both teacher and student are engaged. It follows from this that the teacher must be seen by the student to wrestle with a problem, and, if necessary, to be beaten. The problem must be real, and not a faked-up one designed to come out. Preferably, it should be brought by the student out of his own experience so that the successive steps in forming the abstractions may become apparent. Familiarity with both geometrical and dynamical abstractions plays a significant part in pointing the way towards this reduction of actual physical problems to those of logic. Finally, the precise verbal formulation of the problem in concise terms, as it would appear in a text-book, is itself a crucial educational step. Prof. Levy concluded by stating that in his view it was desirable that every mathematical department should have available as many bits of machines as possible, in order that the student should take them to pieces and re-assemble them, and so seek to isolate the dynamical factors that appear to be in operation during their functioning. In this way the geometrical and dynamical abstractions that require to be made in order to analyse the process from the mathematical point of view would become apparent. This kind of training, consciously applied and consciously appreciated by the student, was essential if he was to play his part *qua* mathematician in modern industry.

Dr. E. A. Maxwell turned to the problem of the teaching of pure mathematics, and in particular he raised the question by what process could the student be encouraged from the beginning to appreciate the importance of rigorous and accurate thinking, and, as part of this, the specific limitations under which the theorems he was using were valid. To this end he stressed the educational value of using the method of contradiction, in a direct form, by 'proving' a number of propositions of the $2 = 1$ type, for the purpose of intriguing the student in the first place. As a consequence, his interest is enlisted in discovering where and how precisely the limitations of the method used have been overstepped. This he illustrated with a variety of examples from a wide range of mathematics. An excellent discussion followed a most interesting morning session.

PHYSIOLOGY AS AN EDUCATION AND AS A CAREER

A JOINT session of Section I (Physiology/Biochemistry) and Section L (Education) of the British Association and of the Physiological Society, held in the Institute of Physiology, University of Glasgow, on September 3, was devoted to a discussion of "Physiology as an Education and as a Career".

In the absence of Prof. A. V. Hill his introductory remarks were read, with evident sympathy and signal effect, by one of his former junior colleagues, Prof. R. W. Gerard, of the Department of Physiology, University of Michigan. Prof. Hill began by recalling what he had said on this topic on several occasions from the 1920's onwards. In these he emphasized the need to free physiology from the bedside attachment of its earlier years and allow it to come in its own right to full stature, as the interpretation of the mechanisms and integrations of normal life. Thus physiology would be brought into a wider service of mankind in the modern fully industrialized State. It has become necessary to spread into new fields the knowledge of the "exquisite structure of the body" and the proper understanding of its functional capabilities and limitations. In all this there is need for first-class brains because in the biological field the data are much more intractable than are those in the inorganic field. This battle for the status of physiology in its own right is slowly being won. Much could be done by capturing early the imagination and interest of the young and securing recruits by means of practical demonstrations and teaching in the schools.

Prof. Hill's Royal Institution Christmas Lectures, later published as "Living Machinery" (Bell; 1927), have shown just how successful this could be.

Dr. J. A. B. Gray (University College, London), who read a paper on "Physiology in Universities", also stressed the emancipation of physiology from its ancillary position in medicine. Physiology is the study of the mechanisms of living species and can be studied at different levels, in cells, in tissues, in organs, in systems and in individuals. It can be applied, not only to man in his life in a more or less normal community, but also to man at the summit of Everest and at the South Pole. It also extends over the widest limits of the comparative field from bacteria to man. He pointed to the growth of physiology as a subject in the faculty of science in one-year, two-year and honours courses. This field offers a unique opportunity for experiment and for the application of physics and chemistry to the fundamental processes of all living organisms. There is opportunity for a much fuller study of man in his place in the modern industrial and engineering world, in the design of instruments and machines to be operated by men and in the determination of the limiting factors in efficiency and endurance in new environments. Much closer links should be forged with psychology; philosophers, too, might profit from a course in physiology.

Thus while physiology must remain as an essential introduction to clinical medicine—the Institutes of Medicine—there are many reasons why ample provision should be made in every university for such courses in the faculty of science to meet other urgent needs.

Mr. H. P. Ramage (Gresham's School, Holt), dealing with "Physiology in Schools", spoke with obvious feeling and emphasis on the pressing need for a balanced education, not just as between science and the other subjects but within the field of science itself. Looking back to the findings of a Royal Commission of 1864 where the place of biology in schools was recognized, he pointed to the very small number of schools, and particularly boys' schools in Britain, where biology takes its proper place in the science curriculum. Biology is, he maintained, a necessary part of general science and general science a necessary part of general education. It is important to realize the value of biology for those who later would not go on to university, as well as for those who would. Much too strong an emphasis is being placed on the inorganic sciences in schools and this gives an unduly mechanistic bias to the minds of the young. Too few biology teachers are available in the schools. The Science Masters' Association is preparing a policy statement in the hope of restoring balance to the present lopsided presentation of science in schools.

Dr. W. Cobb (National Hospital, Queen Square, London), speaking on "Physiology in Medical Research", used the story of Berger's early pure research into changes in electrical potential on the human cerebral cortex, later confirmed by Adrian, to demonstrate how a piece of pure research may later have an extensive practical application. The original research was the patient, disinterested and long unappreciated work of an individual. It was, however, to become in the hands of many others the electroencephalograph, a routine procedure of diagnostic value, widely used in many cerebral conditions. Such an example of the later development of practical applications of pure research is one of many. Physiology will continue to discover new procedures which will later have quite unforeseen usefulness in other fields.

In neurology Dr. Cobb felt that too little work in cerebral physiology is being done in Britain. There is still a gulf, relatively unbridged, between the traditional clinical observational neurologist after the pattern of the great neurologists of the past, and the modern neurophysiologist trained in electronic techniques.

Dr. D. P. Cuthbertson (Rowett Research Institute. Aberdeen) read a paper entitled "Careers for the Physiologist in Agricultural Research". On the successful application of science to agriculture, which is the basic industry in Britain, Dr. Cuthbertson maintained, our future depends; and in this application, physiology has a foremost place. In agricultural research much has been done but much more remains to be done in the extension and orientation of physiological methods to urgent problems. As an example he described briefly the fascinating set of problems associated with digestion in the ruminants, where the problems of animal digestion are complicated by those of microbiology. He did indeed suggest that the physiologist who wishes to enter agricultural research should have a preliminary training in microbiology. He directed attention also to the need for extensive environmental studies, as for example the basic work being done at the Hannah Dairy Research Institute on temperature regulation in cattle. Another expanding area is that associated with the use of insecticides, where problems branch out into many other fields. There are other urgent questions pressing for solution, but where, asked Dr. Cuthbertson, are the physiologists?

Dr. J. Yule Bogue (Pharmaceuticals Division, Imperial Chemical Industries, Ltd.) spoke on "Physiologists in Industry".

Industry has to undertake research, some of it of a fundamental nature, in its efforts to further its own strictly practical aims, for example, the preparation of new pharmaceutical products. In a university post, the young physiologist has to combine research with teaching: in industry he or she has to link together research and routine testing. Just as good research in universities is associated with and indeed stimulates good teaching, so good research in industry is associated with good routine work and might indeed find in it interesting new problems. Physiologists in industry are faced with two groups of questions requiring solution. (*a*) Problems of environmental physiology, for example, in the determination of the conditions in industry which make for maximal efficiency: how man may best be protected from hazards of many kinds, or how the design of instruments may give the least possible fatigue, etc. In this group the medically qualified physiologist is essential. (*b*) Problems which emerge in the study of the action of new products and in the search for further products. These are largely dependent on comparative physiology and may range widely: a medical qualification is not required.

As a preparation for industrial work a wide general physiological experience is best; specialization can be provided in the industry itself when necessary. Dr. Bogue refuted the suggestion that the scientific staff may be under pressure from the management: rather it is a question of the research colleagues supplying the incentive. Generous provision is made in industry for the scientific staff to attend and take part in academic and scientific societies.

Reading a paper on "The Training of Physiologists", Prof. D. H. Smyth (University of Sheffield), who has had a lifelong interest in educational problems, began by speaking of the two different types of individual who might take up physiology as a career. One is the mathematically-minded person who, perhaps, shows his true bent in his hobby of taking the family car to pieces and putting it together again. The other is the biologically-minded individual whose leisure time has been for years expended in early nature studies and who later becomes the serious bird-watcher, fisher or amateur botanist, for he is essentially an outdoor type. While the biologically-minded type is better equipped to see the real physiological problem and has much more highly developed powers of observation, it is the mathematically-minded type who would in the end make a satisfactory analysis of the problem and offer an adequate mathematical solution. In direct contrast to Mr. Ramage, Prof. Smyth was inclined to question the value of biology as a subject in the school curriculum. It is unfortunate that the educationists are as a rule inclined to put their bright pupils into physics and chemistry and the less bright into biology. What is needed is a combination of a good mathematical training and a driving interest in living organisms and how they function. Without the essential motive the more mechanically minded may become just purveyors of gadgets.

In the general discussion that followed these short papers, a questioner was assured that up to the present no difficulty has been experienced in placing women graduates in physiology, and also that no discrimination against women with first-class honours degrees exists in industry.

Dr. Bogue stressed the fact that recently graduated candidates would only be accepted for research by Imperial Chemical Industries, Ltd., if they had first-class honours degrees. He made it clear, however, that many second-class honours graduates were used in the more routine technical work. In his experience industry had found it well worth while to give a first-class honours chemistry graduate as much as three years special training in physiology or pharmacology to get the individual they wished.

There appears to be little accurate knowledge available of the actual number of posts open to physiologists in Britain. In view, however, of the number of unfilled vacancies there seemed to be no likelihood of over-crowding within the next few years. Dr. Gray spoke of even third-class honours graduates having no difficulty in finding suitable work.

Prof. Gerard then spoke of his own interest in this question and in the survey made recently by a committee in the United States, and published under the title "Mirror to Physiology". He discussed the status of physiologists in America and the need for more physiologists there, and also for an improvement in the standards of the lower levels of physiology teaching.

Dr. R. H. Noltie directed attention to the development of physiology teaching in university and college departments of biology and zoology, in isolation from the traditional physiology departments.

The discussion closed with some telling remarks by Sir Charles Lovatt Evans. He reminded the meeting of the difference in rate of development which often means that the good second-class honours man eventually became the first-class researcher who makes the real advances in our knowledge. It was not always true that the first-class honours man became the first-class research worker. Sir Charles thought also that the present concern in many circles for technology and technicians is not without its dangers. Science is a way of thinking and technology is a way of doing things. In his view, there can be no doubt which is the more important.

Thus several points emerged which merit consideration at a future date: (1) The value of the teaching of biology in schools, including some elementary physiology, to all those who will not proceed later to university; (2) the place of biology beside chemistry and physics in the school programme for those who will eventually go to a university; (3) the integration of the teaching of physiology in colleges and universities where this is now being done outside the departments of physiology; (4) the need for a survey of the number of physiology graduates required each year not only in the traditional physiology college and university departments but also throughout the whole field, so that training may be geared to the numbers required and diversified to meet the various new demands.

H. S. D. Garven

SEMICONDUCTOR RESEARCH

In the ten years that have elapsed since the invention of the transistor, the close interaction between academic interest and industrial requirements in the semiconductor field has led to the growth of many industrial and government laboratories with interests in this subject. Because of the connexion with academic work, these laboratories were readily able to grow by attracting graduates of suitable calibre. This has naturally led to much research activity in the semiconductor field, and this is nowhere more pronounced than in the United States. There the transistor was invented, and there alone has it been marketed competitively. It was therefore appropriate that the bi-annual international conference on semiconductors should at last be convened in the United States, having previously met in Britain, Holland and Western Germany. The attractive and spacious campus of the University of Rochester was selected, and the meeting was held during August 18–22 under the chairmanship of John Bardeen. Almost all centres of semiconductor research were represented.

Even with the restrictions placed by the organizers on the number of papers read at the conference, their detailed discussion is not possible here. The general headings have not changed very much since the last meeting in 1956[1], but some changes of emphasis have occurred in the interim and will now be surveyed.

Excitons. There was considerable interest in excitons at the 1956 meeting[1], with particular reference to the pioneer work of E. F. Gross (Leningrad) and S. Nikitine (Strasbourg), who had noted exciton spectra. Their experiments, which were still questioned in 1956, have now been largely accepted.

and they both reported at Rochester on their work. In particular, Gross showed how the quadratic diamagnetic Zeeman effect, rather than the linear paramagnetic effect, was observed in the cuprous oxide exciton spectrum. This suggests that the excitons behave here like positronium atoms, with equal effective masses for electron and hole.

The propagation of photoconductivity in single crystals of cadmium sulphide over distances of millimetres had been attributed tentatively to the properties of excitons[1]. This surprising result was reported in 1956 in a paper by Balkanski and Broser: the latter author now favours a different explanation of the results, namely, the scattering and re-absorption of luminescent radiation. He described experiments which furnish good evidence for his present view. In other papers (T. Muto, Tokyo; B. Goodman, Missouri; W. Martienssen, Göttingen) the role of excitons in ionic crystals was also discussed.

Evidence for the creation of excitons in germanium and silicon has recently been obtained from the fine structure of the absorption edge. British work by G. G. Macfarlane and his colleagues at the Royal Radar Establishment, Malvern, as well as the theoretical interpretation by R. J. Elliott (Oxford) was given due prominence at the meeting. In the latter contribution, the new material included a discussion of the effect of the Coulomb interaction, previously neglected. Work at the Lincoln Laboratory (B. Lax *et al.*) has confirmed some of these results, and an exciton life-time of the order of 10^{-11} sec. has been suggested for germanium in zero field. Fine structure in the intrinsic recombination radiation (J. R. Haynes *et al.*, at the Bell Telephone Laboratories) is consistent with this optical absorption work. There is, therefore, now firm experimental evidence for the existence of excitons in both elemental and compound semiconductors. It is hoped to learn more from these experiments about the exciton spectra, and about the phonons which can take part in their excitation.

Optical and magneto-optical effects. There has also been considerable progress in this field since 1956. In a magnetic field the electron states in a band are displaced on an energy scale to give rise to the so-called Landau levels. Since the optical transitions into the conduction band depend on the density of final states, one would therefore expect oscillations if the absorption coefficient is plotted against photon energy. Such oscillations due to interband transitions have been found, notably in germanium, InSb and InAs (E. Burstein *et al.*, Philadelphia; B. Lax, Lincoln Laboratories), and progress has been made in the interpretation of the large amount of information now available.

Low-temperature optical absorption experiments, made with the view of finding evidence for the excitation and ionization of impurities, have been pursued by H. Y. Fan *et al.* (Purdue), at liquid-helium temperatures and out to 300μ, on various concentrations of impurities in silicon and germanium. A significant development here is that in recent years the simple hydrogen-like model for the impurities has been replaced in the interpretation of experiments of this kind by the more refined model of W. Kohn. Upon applying a magnetic field the Zeeman splitting of the excited states can be observed. In addition to the magneto-optical interband oscillations mentioned above, a similar effect must be expected if the electrons are initially in impurity states, and this has also been observed (R. F. Wallis, Washington; W. S. Boyle, Bell Telephone Laboratories).

Reviews of work on certain infra-red phosphors (G. F. J. Garlick, Hull) and of conductivity and luminescence of diamonds (E. W. J. Mitchell, Reading) were also given.

Recombination. So far as the theory is concerned, recent efforts in this field have been devoted to the investigation of more and more mechanisms with the view of explaining the experimental results, which are still poorly understood as regards absolute values, though the situation is better if one restricts attention merely to the explanation of shapes of curves. At the meeting, reasons for the large capture cross-sections ($\sim 10^{-14}$ cm.^{2}) of traps in germanium and silicon were put forward (M. Lax, Bell Telephone Laboratories), and the part played by the Auger process in recombination was discussed. The main weight of research, however, has been concentrated on accumulating more experimental information. The work on the effect of dislocations on recombination-rates should here be mentioned as an active field (A. F. Gibson, Royal Radar Establishment, Malvern; P. Baruch, Paris; R. K. Müller, Minneapolis; H. Kawamura, Tokyo). In particular, surprisingly detailed structure was reported in the recombination radiation through dislocation in germanium at 20° K. (C. Benoit à la Guillaume, Paris).

Perhaps the most interesting 'hard' results (because they are older and confirmed) to be discussed were those on deep-level impurities in germanium, where different experimental methods led to the same picture, namely, the possibility of multiple ionization of the impurities (W. W. Tyler, Schenectady). Though the statistics of recombination through such centres appears to be well understood, a satisfactory calculation of the position of the energy-levels is still outstanding.

Hot electrons, high-field effect and impact ionization. The term 'hot electrons' is due to Shockley (1951). (It is perhaps not generally known that the concept of effective electron temperatures in solid state physics appears to have been used first by H. Fröhlich[2].) The three concepts, hot electrons, high-field effect and impact ionization, are closely related, since a high electric field causes electron-hole pairs to be created by impact ionization—a conduction electron knocks an electron out of the valence band—and it also causes electrons to gain more energy than they can lose to the lattice, so that they can attain a temperature greater than that of the lattice. Among the main advances made since 1956 is the now widespread appreciation that one can realize, by impact ionization, quantum efficiencies in excess of unity. This is largely due to the work on the inner photoelectric effect by the Czech school (J. Tauc, Prague).

Another interesting effect is the evidence of anisotropy in electric conduction at high fields, which can have the effect that some valleys (of the energy surfaces in k-space) become hotter than others, with a consequent transfer of electrons from the hotter to the colder valleys (W. Sazaki *et al.*, Tokyo). Attention was also directed to the importance of electron–electron scattering with the resultant emission of optical phonons as a loss mechanism for hot electrons (J. B. Gunn, Vancouver). Interesting results, recently published in *Physical Review Letters*, on the use of pulsed current-voltage measurements to show the incidence of impact ionization in n-type single crystals of InSb were also presented (M. C. Steele and M. Glicksman, Princeton).

Other transport effects. In this field a large amount of detail has been filled in, and some was reported at the meeting, on both the older and the newer semiconductors. The main Russian contribution may be mentioned here, namely, to direct attention again to the low-mobility semiconductors (A. Joffé, Leningrad), which may raise fundamental problems. For example, if the mean free path of electrons is of the order of: $l = 10^{-8} \sqrt{(m_e/m)}v$ cm., where v is the mobility and m_e the effective mass of electrons, then l is less than atomic distances for $v < 10$ cm.^{2}/volt-sec., and therefore ceases to have a meaning. The concept of energy-bands itself may become inapplicable. Impurity scattering and mobility theory would both require extensions for this class of substances. The view was also expressed that the change of electrical properties during melting suggests that the zone structure of solids depends only on short-range order. Great difficulties, however, stand in the way of understanding disordered structures, to which a paper by C. Domb *et al.* (London) was devoted.

Substances which exhibit impurity-band conduction present some features of a disordered low-mobility system, but little progress in the understanding of this phenomenon appears to have been made, though interesting papers on this topic were presented at the meeting (germanium, H. Fritsche, Chicago; silicon, T. Longo *et al.*, Purdue; InSb, R. J. Sladek, Pittsburgh).

Low-temperature photoconductivity in silver halides was described by J. W. Mitchell (Bristol) and F. C. Brown (Urbana).

Bonds. In connexion with the renewed attempt to look beyond the band picture, a number of substances have been studied recently the properties of which may possibly be more readily understood in terms of some chemical-bond picture. A curiosity among these is the compound AuCs, with two elements of the first group, which is a large-gap ($E_g \simeq 2 \cdot 9$ eV.) semiconductor (W. E. Spicer and A. H. Sommer, Princeton). Also of interest are the $A^{III} B^{VI}$ compounds from the third and sixth group (for example, GaTe), which have been investigated by E. Mooser *et al.* (Ottawa). These are semiconductors although they have nine valence electrons per anion, that is, one more than is normal in such semiconductors.

Bands. There was at the 1956 meeting an almost complete absence of energy-band calculations[1], but this was not true of the 1958 meeting. Several American workers have recently reconsidered the status of the one-electron approximation, and W. Kohn (Pittsburgh) spoke on the justification of the one-electron effective-mass approximation from the many-electron Schrödinger equation. The effect of a magnetic field may require further consideration here. The use of potential operators in band calculations was also discussed. Particularly the $\mathbf{k} \cdot \mathbf{p}$ approach (E. O. Kane, Schenectady) has in recent years proved very useful, though it was suggested by J. C. Philips (Bell Telephone Laboratories) that rather large corrections may be required. Band forms discussed at the meeting included ZnS (J. L. Birman, Bayside), InAs (F. Stern, Silver Springs), GaAs (R. Braunstein, Princeton), apart from silicon and germanium.

Surfaces. There has been steady consolidation in this field, which was surveyed by A. Many (Jerusalem). The distinction between fast and slow states appears to remain useful, and the origin of the fast states is still not understood, though they are believed to reside in the transition region from the bulk material to the surface oxide. The time-lag which usually exists before experiments on the bulk material are attempted for a restricted part of the surface layer is, however, shortening, and optical, magnetic and transport properties of surfaces were discussed (for example, by J. N. Zemel and R. L. Petritz, Silver Springs). The adsorption on germanium and silicon appears to follow a logarithmic rate law (S. Wolsky, Waltham), familiar in oxidation and chemisorption studies. Reproducible 'clean' ('Farnworth') surfaces can be produced by ion-bombardment or heating techniques, and these have now become standard procedures.

The meeting closed with a very useful summary session, in which L. Apker, W. H. Brattain, H. Brooks, C. Herring and D. Polder took part, and one may express the hope that this will become an increasingly important pattern of future meetings. The proceedings will be published early in 1959 in the *Journal of the Physics and Chemistry of Solids*, and the next meeting will probably take place in Prague in 1960.

THE EUROPEAN NUCLEAR ENERGY AGENCY

UNDER the title "The European Nuclear Energy Agency and the Eurochemic Company*, the Organization for European Economic Co-operation has published the first report of its Steering Committee for Nuclear Energy. It includes the Statute for the European Nuclear Agency, which the Committee recommends the Council should adopt, as well as two draft conventions, one on the establishment of security control in the field of nuclear energy and the other on the constitution of the European Company for the Chemical Processing of Irradiated Fuels (Eurochemic). The former is to be recommended to member governments for signature and the latter is to be submitted for signature to the governments interested. Amendments to its Statute are also proposed by the Study Group for the Chemical Processing of Irradiated Fuels and authorization is requested for expenditure by the Study Group of 500,000 European Payments Union units of account. The Study Group also recommends that the proposed plant should be located at Mol in Belgium, but if it were decided later to construct a large plant the most suitable site is considered to be that proposed by Norway. The present plant is estimated to cost

* Organisation for European Economic Co-operation. European Nuclear Energy Agency and the Eurochemic Company. First Report of the Steering Committee for Nuclear Energy to the O.E.E.C. Council. Pp. 192. (Paris: Organisation for European Economic Co-operation, 1958.) 750 French francs; 12*s.*; 2 dollars.

12 million E.P.U. units of account and, including research, would require a staff not exceeding 400–450.

The Steering Committee expects shortly to submit proposals for the joint construction or operation of two experimental reactor projects (boiling water reactor and homogeneous aqueous reactor) and is also to report shortly on the measures at present under discussion for liberalization of international trade. It is also to submit proposals regarding training, and particularly the assistance to be given to universities and higher technical colleges of member countries for training specialists; health and safety, particularly the examination of projects for the discharge of radioactive waste, the evaluation of reactor hazards, and the international transport of highly radioactive materials; and liability and transport, particularly the drawing up of common rules concerning third-party liability in the nuclear field. Annexes to the report include a general description of the recommended processing plant, the text of the proposed conventions and the amended Statute of the Study Group, as well as the proposals of the working groups on experimental reactors and on nuclear power stations for their co-operative development in Europe. There is also a summary of the national programmes for building nuclear power stations in Austria, Belgium, France, Western Germany, Italy, the Netherlands, Sweden, Switzerland and the United Kingdom.

On the basis of this report, the Council, on December 17, 1957, adopted the Statute of the European Nuclear Energy Agency, and the International Convention on Security Control was signed by member countries of the Organization for European Economic Co-operation on December 20. The text of this Statute and the Convention (see *Nature*, 181, 952; 1958) are also appended to the report, which, with the details of membership of the study groups, working groups and working parties and of the Steering Committee itself, is a particularly useful reference document on the present development of nuclear energy in Europe.

THE TASMANIAN MUTTON-BIRD

THE Tasmanian mutton-bird, *Puffinus tenuirostris* (Temminck), is known to ornithologists as the short-tailed or slender-billed shearwater, and was known to the Tasmanian aborigines as 'yolla' and to the white seafarers of Bass Strait as the 'yowler'. Historically it is recorded earlier than white settlement of Australia; sociologically it has importance as the only example of commercial wildfowling successfully surviving in Australia and in being the mainstay of that interesting community, the Cape Barren Islanders; scientifically, it amazes naturalists through the astonishing regularity of its breeding time-table, its widespread migration and its uncannily accurate homing each year to its exact nesting site. It also occurs in such abundance that it could quite well be Australia's most numerous bird. An interesting account of the bird has been prepared by D. L. Serventy*.

Puffinus tenuirostris is a long-lived bird, and, for its size, has an unusually lengthy period of sexual immaturity. Female birds begin to breed at 5–7 years of age and males at 7–8 years. Immature birds do not make a landfall, once they leave their natal islands as fledglings, until they are 3–4 years of age.

The sexually mature, breeding birds return from their migration to the nesting islands in the last week of September, and by then gametogenesis is well advanced. Burrows are actively scratched out, and vocal performances enliven the rookeries at night. Though egg-laying does not begin until the third week in November, a striking behavioural change occurs at the beginning of November. The birds vacate the islands entirely, and do not return again until the onset of egg-laying.

The exodus follows immediately after fertilization, and the birds leave for the open sea while the single very large egg matures (it weighs about 85 gm. and is about 16 per cent of the female's body-weight). Though this pre-egg-laying exodus was known in the Tasmanian mutton-bird from early times, it was not detected in other petrels until comparatively lately.

Egg-laying starts about November 20–22 and ends about November 30–December 2. The calendar is invariable from year to year and from rookery to rookery, though these are spread through eleven degrees of latitude—from near Ceduna, in South Australia, to southern Tasmania—adjacent to seas which differ widely in temperature, chemical composition and currents. Year-to-year variations in the local sea conditions, or the weather, have no influence on the breeding calendar, which is the same now as when the earliest observers wrote their accounts more than a hundred years ago. This surprising constancy has yet to be fully explained.

When the birds return to their nesting islands for the egg-laying the male gonad has dwindled drastically in size, and the seminiferous tubules are in a state of fatty metamorphosis. No other avian species shows a more rapid collapse of the testis, though this may be characteristic of the petrel group. When the egg is laid, the female departs to the sea to recuperate.

The newly hatched chick is rarely tended continuously by the parents for longer than two days and is then left alone by day. Both parents share in the feeding, which takes place at intervals, and the young bird may have to undergo lengthy fasts of several days between Gargantuan banquets of krill. The growth-rate is rapid and the fledgling may come to exceed the weight of a large adult in little more than a month after hatching. The young birds emerge from the burrows at night, vigorously exercise their wings and at length make their own departure from the natal islands. This exodus of the fledglings usually occurs from the third week in April to the first week in May.

The nature of this migration has long been a matter of speculation. Some ornithologists were loath to believe that the birds in the northern Pacific could be of the same breeding stock as the Australian birds. The first ornithologist to suggest that the north Pacific birds were Australian birds on migration was A. J. Campbell. It was only in 1955 that the first positive proof was obtained by a banding record.

---

* *Aust. Mus. Mag.*, 12, No. 10 (June 15, 1958).

The route followed on migration appears to be largely conditioned by the direction and strength of the prevailing winds. By flying a roundabout 'figure of eight' course over the Pacific the birds are assisted by wind. The only place where they meet with any strong wind resistance is on the southward leg of the route when returning to Australia in the spring. Here they have to battle against the strong south-east trade winds which blow all the year round across the Pacific. Wherever they cross this belt the birds encounter strong winds.

These youthful first- and second-year birds share in the general migration of the more mature birds, though some individuals among them may continue to spend the southern summer in the north. Such behaviour is not unusual with other trans-equatorial migrants, such as the waders. Even though they may migrate south with the breeding birds, the first- and second-year individuals do not come ashore but remain at sea. It is only when they reach three years of age that they effect a landfall, and then only comparatively briefly, between hatching time in January and the third week in March. The fourth-year birds show a similar behaviour, but more appear to come ashore at this age than at three years, and some individuals even put in an appearance earlier in the season, namely, from mid-December onwards. When they are five years and older the birds appear to come ashore with the breeding adults, though they remain unmated.

Once a bird begins to breed on a particular site, it tends to return to the same spot each season with remarkable fidelity. Often it remains mated with the same partner. On Fisher Island there are several examples of birds which have bred together each year since observations first began in 1947.

AN ANTIBONDING MORSE POTENTIAL

By ROBERT W. KEYES

Westinghouse Research Laboratories, Pittsburgh 35, Pennsylvania

MORSE has proposed a three-parameter function,

$$\mu(r) = L[\exp\{-2\beta(r-a)\} - 2\exp\{-\beta(r-a)\}] \quad (1)$$

to represent the potential function for the motion of the nuclei of a diatomic molecule[1]. The function (1) has proved quite useful in the understanding of the properties of diatomic molecules, since Morse was able to solve the one-dimensional Schrödinger equation for motion in the potential $\mu(r)$, and thus to express the molecular energy-levels in terms of the parameters L, β and a.

I wish to suggest how the potential for the antibonding state corresponding to (1) can be represented by a similar function. Compare function (1) with a one-electron system in which the quantum mechanical theory easily leads to an approximate analytical formula for the potential for nuclear motion, namely, the hydrogen molecule ion. In the approximation in which the wave function is considered to be a linear combination of atomic 1*s* functions and the Coulombic field of the second nucleus is considered as a perturbation, the potential in question is:

$$\mu(r) = \mathrm{f}(r)\exp(-2r/b) - \mathrm{g}(r)\exp(-r/b) \quad (2)$$

where $\mathrm{f}(r)$ and $\mathrm{g}(r)$ are algebraic functions of r, the distance between the two protons, and b is the Bohr radius[2].

Now, in (2) we assume that the important dependence on r arises from the variation of the exponentials, rather than of the algebraic functions. That is, we make the approximations $\mathrm{f}(r) = f_0$ and $\mathrm{g}(r) = g_0$, where f_0 and g_0 are constants. It is then found that the minimum of the potential (2) occurs at $r = c = b \log(2f_0/g_0)$, and that (2) can be written:

$$\mu(r) = f_0 \exp(-2c)\,[\exp\{-2(r-c)/b\} - 2\exp\{-(r-c)/b\}] \quad (3)$$

But (3) is the same as (1) with $\mathrm{L} = f_0 \exp(-2c)$, $\beta = 1/b$, and $a = c$.

Thus, it is seen that the first and second terms of the Morse potential (1) correspond to the first and second terms of (2), respectively. The theory[2], however, reveals the physical origin of the terms of (2). The first term arises from Coulombic interactions of the protons and electron, and is always repulsive. The second term arises from the resonance or exchange integral, and, for the state in question, is attractive. Thus, we identify the first and second terms of the Morse potential with the Coulombic and exchange effects, respectively.

The usefulness of this interpretation arises from the fact that the potential function for the antibonding electronic state of the hydrogen molecule ion differs from the bonding state only in the sign of the exchange integral, except for an orthogonality correction[2]. Thus we would expect that the potential for the antibonding electronic state arising from the atomic functions which give rise to (1) can be approximately written as:

$$\mu_{ab}(r) = L[\exp\{-2\beta(r-b)\} + 2\exp\{-\beta(r-b)\}] \quad (4)$$

The validity of the approximations involved in the use of (4) to represent the antibonding potential is checked in Fig. 1, where the bonding and antibonding potentials given by the simple perturbation theory for orbitals composed of linear combinations of atomic 1*s* functions for the hydrogen molecule ion are plotted as solid lines. A Morse function (1) can be chosen to give a quite good fit to the bonding potential. The fact that the algebraic functions $\mathrm{f}(r)$ and $\mathrm{g}(r)$ have been replaced by constants shows up in that the value of β which gives the best fit of (1) to (2) is not exactly $1/b$. According to (4), the antibonding potential corresponding to (1) can be obtained by simply changing the sign of the second term of (1). This antibonding potential is also plotted in Fig. 1 as a dashed line, and is seen to be a good approximation to the result of the perturbation theory.

In a system in which many electrons contribute to the bond between two atoms, in general the contribution of some of the electrons to the bonding potential will be bonding and the contribution of

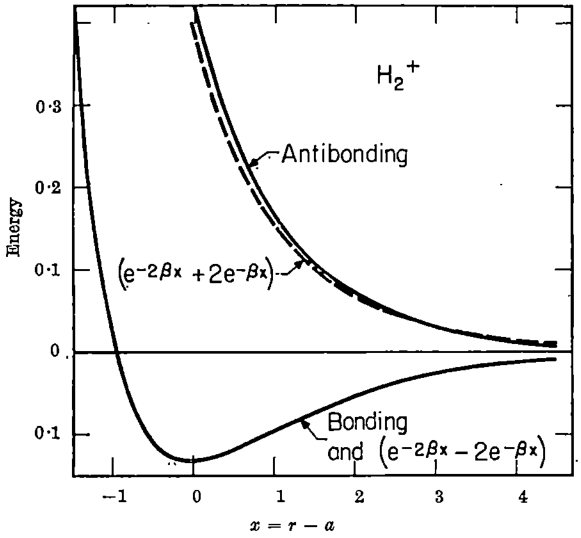

Fig. 1. The solid curves represent the nuclear potentials for the bonding and antibonding electronic states of the hydrogen molecule ion. The dashed curve is obtained by fitting a Morse function to the bonding potential and reversing the sign of the second term

other electrons to the potential will be antibonding. Thus, if it is assumed, (1), that the total potential, $V(r)$, can be constructed by addition of contributions from individual electrons, and (2) that the parameters L, a and β are the same for all electrons involved in a particular bond, then $V(r)$ is a linear combination of the potentials $\mu(r)$, equation (1), and $\mu_{ab}(r)$, equation (4). It is easily seen that these linear combinations are also potentials of the Morse form.

If the total number of electrons which contribute to $V(r)$ is constant, all such linear combinations form a one-parameter family of Morse functions. Some members of one of these families are plotted in Fig. 2. An extensive analysis of the properties of such families of Morse functions will be described in a separate communication[3]. The particular result of the analysis which will be used here is that the parameter β is the same for all members of a family and that the vibrational frequencies, ω_e' and ω_e'', associated with two members of a family are related to the nuclear separations at the potential minima, r_e' and r_e'', by:

$$\frac{\omega_e'}{\omega_e''} = \frac{\exp(-\beta r_e')}{\exp(-\beta r_e'')} \qquad (5)$$

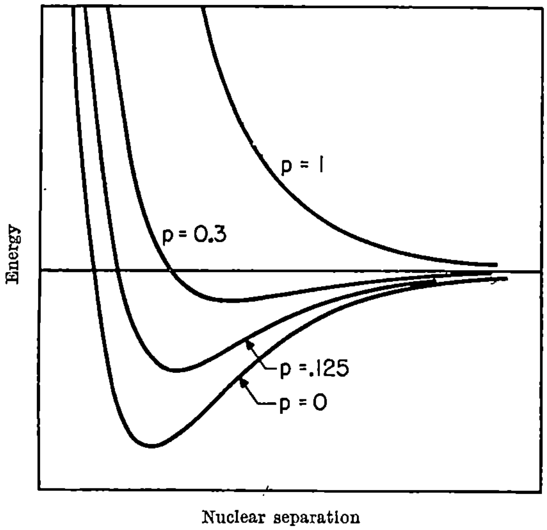

Fig. 2. Some members of a one-parameter family of Morse potentials of the type described in the text. The parameter p is the fractional amount of antibonding potential in the total potential, namely, $V(r) = p\mu_{ab}(r) + (1-p)\mu(r)$

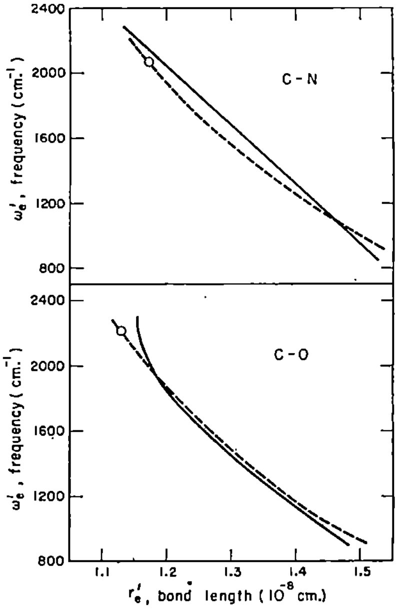

Fig. 3. Comparison of empirical frequency versus bond-length curves, the solid lines (ref. 4), with those calculated according to equation (5), the dashed lines, from the properties of the ground-state of the corresponding diatomic molecules. These ground-states are indicated by the points on the curves

To use the concepts introduced here, we assume that various states of a particular molecular bond all involve the same number of electrons, and differ only in their distribution of electrons between bonding and antibonding states. Then equation (5) represents a correlation between the vibrational frequencies and internuclear separations of the states of the bond. It will be shown elsewhere that the present model gives a reasonable account of the relations between the properties of some familiar diatomic molecules in various states of excitation[3]. Here we may compare equation (5) with the empirical frequency versus bond-length curves recently given by Layton, Kross and Fassel[4] for the C—N and C—O bonds in polyatomic molecules.

To make this comparison we have evaluated the parameter β for the C—O and C—N bonds from the anharmonicities of the ground-states of the respective diatomic molecules, and have used for ω_e'' and r_e'' the values observed for these states[5]. The curves ω_e' versus r_e' which are then found from equation (5) are plotted in Fig. 3, together with the curves given by Layton *et al.* It is seen that in both cases the correspondence of our calculated curve with the empirical one is quite close.

MODE OF ACTION OF INTERFERON

By Dr. ALICK ISAACS and Dr. DEREK C. BURKE
National Institute for Medical Research, London

INTERFERON is the name that was given to a substance produced by the interaction of inactivated influenza virus with cells[1]. Interferon inhibits the growth of a variety of viruses and it seems to be the mediator of the phenomenon of virus interference. Its antiviral action, which includes ribonucleic acid viruses like those of the influenza group and deoxyribonucleic acid viruses like those of the pox group, seems to be directed at some early stage in the virus multiplication cycle within cells.

It was found earlier that when heated (56° C.) influenza virus was incubated with chick chorio-allantoic membranes *in vitro*, interferon was formed for a period of about 24 hr. only; but a second inoculation of heated virus then produced a second 'crop' of interferon[2]. This finding led to an investigation of other stimuli which might produce a second crop of interferon. It was observed that, in general, only virus capable of inducing production of interferon in untreated cells had the same effect in cells previously incubated with heated influenza virus. But one exception was found: live influenza virus, which does not normally produce interferon during the course of its multiplication in normal chorio-allantoic membranes, did so when incubated with membranes in which interference had been induced by previous incubation with heated influenza virus[3]. Since interference seems to be mediated through interferon, which is itself incapable of reproduction, it was of interest to see whether live virus would produce interferon in cells previously treated with interferon.

The experiment was carried out as follows. Three sets of chorio-allantoic membranes were used—one experimental and two control. Sufficient interferon to produce about 95 per cent interference with the growth of influenza virus was added to two sets of membranes, and Earle's buffered salt solution to the third. The membranes were incubated at 35° C. in bottles in a shaking machine delivering 86 strokes a minute with an amplitude of 1 in. After 3 hr., the membranes were removed, washed thoroughly and incubated overnight in buffer. Next day the membranes were incubated in the same way, but two sets with live influenza virus (strains *MEL* or *PR*8) and the third with buffer; the amount of influenza virus used corresponded to an estimated multiplicity of about one *ID*50 per cell. After 3 hr. the membranes were again washed and incubated overnight with buffer. The fluids were removed, and titrated for hæmagglutinin, in order to demonstrate satisfactory growth of influenza virus in control membranes, and inhibition of virus growth in membranes pre-treated with interferon. The fluids were next dialysed overnight against buffer at *p*H 2 (a procedure which inactivates virus but leaves interferon unaffected), then dialysed back to *p*H 7 and centrifuged to remove precipitates before testing for interferon content.

The fluids from the second 24-hr. period were tested for their ability to inhibit the growth of influenza virus in small pieces of chorio-allantoic membrane *in vitro*[1]. At the same time, the fluids from the first 24-hr. incubation period were usually tested for control purposes and they invariably showed no interferon. The results of one experiment of this kind are shown in Table 1, where the interferon content of the fluids is expressed as the amount of inhibition ($\log_2$) of virus growth produced in the test system.

Table 1. PRODUCTION OF INTERFERON BY LIVE VIRUS IN CELLS PREVIOUSLY TREATED WITH INTERFERON

First inoculum	Second inoculum	Yield of interferon* ($\log_2$)
Interferon	Buffer	0·2
Buffer	Live influenza virus	1·1
Interferon	Live influenza virus	5·7

* Expressed as the amount of inhibition ($\log_2$) of virus growth produced in the test system. An inhibition of $\log_2 = 2$ is significant at the 1 per cent level (ref. 1).

It is seen that treatment of chorio-allantoic membranes with interferon followed by buffer did not produce interferon in significant amount, nor did growth of virus in previously untreated membranes. But in membranes pre-treated with interferon a highly significant amount of interferon was produced.

This type of experiment can now be reproduced regularly; but difficulties were encountered at first. In one group of experiments with a particular batch of interferon, the interferon appeared to be reproducing itself; this was traced to the fact that this batch contained a small amount of live influenza virus resulting from the use of incompletely inactivated virus in the production of this batch of interferon. When the interferon was incubated with chorio-allantoic membranes, some multiplication of the virus presumably occurred before interference was established, and this virus was then able to induce further production of interferon in the membranes which had adsorbed interferon earlier. In order to avoid this difficulty in later experiments, each batch of interferon was treated at *p*H 2 to destroy any live virus. Another point was that an adequate amount of interferon was required for the priming dose, as it was found that the greater the priming dose of interferon the greater the yield following incubation with live virus. It was also found necessary to use a dose of live virus sufficient to infect all cells in the first cycle; when fewer cells were infected a smaller yield of interferon resulted within the period of incubation. One final difficulty was that some batches of live virus produced interferon in untreated membranes. The reason for this may have been the use of old virus seeds in which interferon apparently accumulates. This requires further investigation, but from the point of view of the present experiments the difficulty was avoided by using fresh 24-hr. harvests of virus.

These experimental difficulties, once resolved, tended to confirm the fact that live virus produced interferon in cells previously treated with interferon. This might be explained by assuming that interferon

Table 2. EFFECT OF HEAT ON THE ABILITY OF ULTRA-VIOLET IRRADIATED INFLUENZA VIRUS TO PRODUCE INTERFERON IN UNTREATED AND INTERFERON-TREATED CELLS

First inoculum	Second inoculum	Yield of interferon ($\log_2$)
Buffer	Ultra-violet inactivated influenza virus	2·9
Interferon	Ultra-violet inactivated influenza virus	4·1
Buffer	Ultra-violet inactivated virus heated 1 hr. at 60° C.	0
Interferon	Ultra-violet inactivated virus heated 1 hr. at 60° C.	0

was taken up by the cells, from which it could later be released by live virus. But ground extracts of the chorio-allantoic membrane prepared 24 or 48 hr. after inoculation of a large dose of interferon showed a negligible content of interferon. It seems more likely, therefore, that the live virus induced synthesis of interferon. This is supported by the experiment summarized in Table 2. In this experiment the technique was the same as in the experiment shown in Table 1.

The results show that when irradiated virus is heated to destroy its ability to produce interferon in untreated membranes, it loses its ability to do so in interferon-treated membranes.

These experiments suggest that cells treated with interferon and afterwards infected with live virus produce interferon instead of live virus. Interferon appears to be a protein, and it may therefore be an analogue of a protein normally formed during virus synthesis. If so, the mode of action of interferon could be described as deflecting virus synthesis from the production of a normal protein intermediate towards the production of interferon, which represents a 'blind alley' in virus production. Virus interference would then result from the same re-direction of the virus synthetic pathway.

With regard to the possible functions of the protein in virus multiplication, some recent work on phage may be relevant. Burton[4] has described experiments which show that early during phage growth, synthesis of phage deoxyribonucleic acid is preceded by synthesis of protein that is not a precursor of phage protein; and Stent[5] has produced evidence which leads him to suggest that at the onset of phage infection, phage deoxyribonucleic acid may transfer its information to a newly synthesized protein. If an animal virus replicates by transferring the information in its ribonucleic acid to a newly synthesized protein, then interferon could be an analogue of that protein. We might describe these results in the following terms: viral ribonucleic acid supplies both the pattern and the stimulus for replication, the pattern being mediated through the production of a protein. Interferon supplies only the pattern for replication. In the present experiments, viral ribonucleic acid infecting interferon-treated cells would find the pattern for replication already established by interferon, and the viral ribonucleic acid would then supply only the stimulus to replicate.

DEGRADATION OF DL-METHIONINE BY RADIATION

By JIŘINA KOPOLDOVÁ, JAROSLAV KLOUŠEK, ARNOŠT BABICKÝ and JINDŘICH LIEBSTER

Biological Institute of the Czechoslovak Academy of Sciences, Prague

IN our previous communication[1,2] the degradation of DL-methionine by X- and β-rays was studied chromatographically with special regard to the degradation products containing sulphur-35.

In experiments reported here the quantitative relations between the irradiation dose, the amount of ammonia liberated and the decrease of methionine were determined. The ninhydrin-positive degradation products of methionine, as well as of methionine sulphoxide, sulphone and sulphoximine, have now been identified.

The experimental procedure employed here was essentially the same as previously described[1,2]. The irradiation intensities were determined with a ferrous/ferric[3] and with a benzene[4] dosimeter and amounted to 2×10^{18} eV./ml./min. Volumes of 1–1·5 ml. were irradiated under standard conditions in methacrylate or paraffin Conway vessels closed by aluminium foil. Doses of $0{\cdot}2$–4×10^{20} eV./ml. of X-rays and $5{\cdot}7 \times 10^{20}$ eV./ml. of γ-rays were used.

Ammonia was determined quantitatively by Conway's method. The decrease of methionine was determined by photometric evaluation of the chromatograms[5]. After chromatographically pure methionine-^{35}S had been added to the solution to be irra-

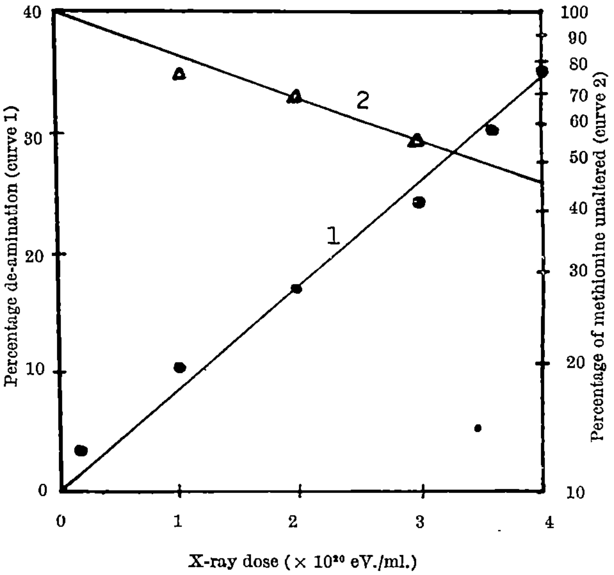

Fig. 1. Relation of the degree of de-amination and the decrease of methionine to the irradiation dose

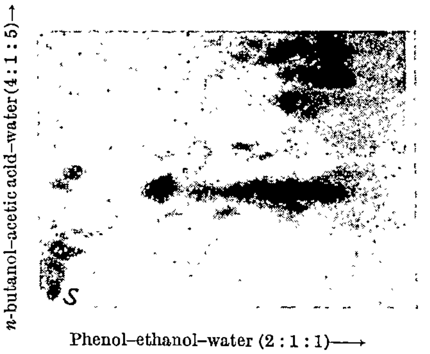

Fig. 2. Autoradiogram of the two-dimensional chromatogram of a methionine-^{35}S solution 90 days old. *S*, start

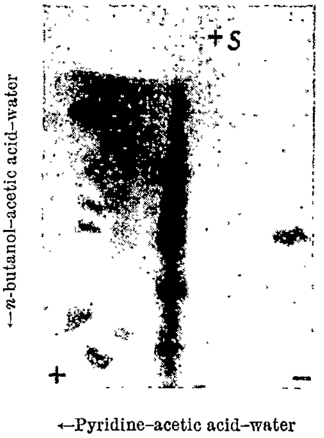

Fig. 3. Autoradiogram of the combined electrophoreto-chromatogram of methionine-^{35}S. *p*H 5·6. *S*, start

diated, the methionine content was determined radiometrically. The irradiated solutions were chromatographed, the spots of methionine-^{35}S were cut out, oxidized by a mixture of cupric nitrate and perchloric acid, the sulphate formed was dissolved in hydrochloric acid and precipitated as barium sulphate and its radioactivity determined. Chromatography, electrophoresis and autoradiography were performed as previously described[1,2]. The degradation products were identified by chromatographic comparison with standard compounds. α-Aminobutyric acid was identified by infra-red spectrography. The amount of sulphate in the irradiated solutions to which tracer quantities of methionine-^{35}S had been added was determined by precipitation as barium sulphate and radioactivity measurement.

The relation of the degree of de-amination and the decrease of methionine to the irradiation dose are given in Fig. 1. It can be seen that the degree of de-amination is a linear function of the irradiation dose, whereas the decrease of methionine content is an exponential function. The amounts of sulphur oxidized to sulphate were 0·21, 2·1 and 8·2 per cent for doses of 0·2, 2 and 3·6 × 10^{20} eV./ml. respectively. The amount of volatile compounds containing sulphur-35 (mainly CH_3SH) increased during irradiation; it amounted to 1·4 per cent of the total radioactivity at a dose of 2 × 10^{20} eV./ml. and 2·5 per cent at 3·6 × 10^{20} eV./ml.

After the irradiation of a DL-methionine solution with a dose of 3·6 × 10^{20} eV./ml. the following compounds were identified on a two-dimensional chromatogram: α-aminobutyric acid, threonine, alanine, aspartic acid, serine (in order of decreasing intensity of the spots). The decarboxylated products mentioned by Sahasrabudhe *et al.*[6] were not studied in detail. Their basic character was ascertained by paper electrophoresis. Methionine sulphoxide, meth-

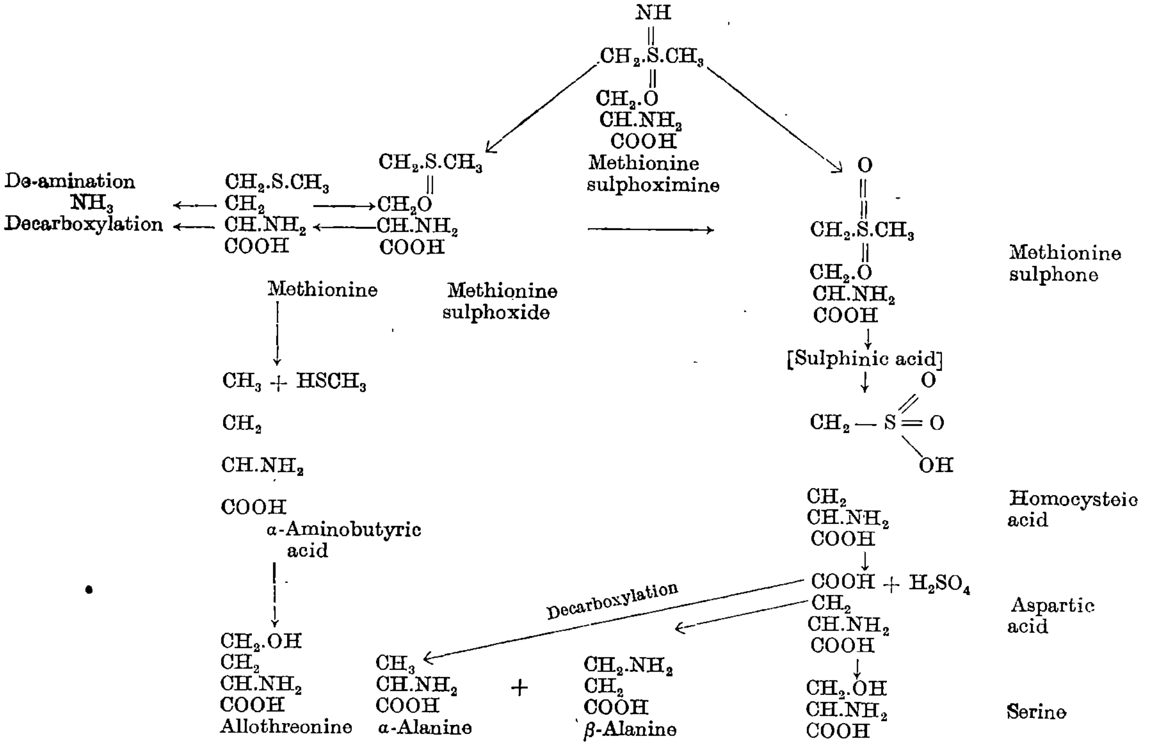

Fig. 4. Reaction pattern of the radiation decomposition of methionine-^{35}S (ninhydrin-positive compounds)

ionine sulphone and homocysteic acid, previously[1,2] identified as methionine radiation degradation compounds, were also detected.

Similarly, on the two-dimensional chromatogram of methionine-^{35}S (Fig. 2) 6 ninhydrin-positive and radioactive substances, 5 ninhydrin-positive only and 22 radioactive only compounds were found. The radioactive only compounds were predominantly acidic, as was ascertained by electrophoresis combined with chromatography and autoradiography (Fig. 3). These compounds are among the products of the de-amination process.

Irradiation of methionine sulphoxide with an identical dose under standard conditions gave the same compounds on the two-dimensional chromatogram as methionine, but they were in a different quantitative ratio ; the intensities of the spots due to homocysteic acid and aspartic acid especially were greater than those from methionine. When methionine sulphone was irradiated in the same way only spots of aspartic acid, homocysteic acid and serine were found.

On the basis of the comparison of the chromatographic picture of the irradiated solutions of methionine, methionine sulphoxide, methionine sulphone and methionine sulphoximine it is possible to summarize the reactions occurring during the decomposition of methionine by radiation (Fig. 4).

When solutions of methionine and methionine sulphoxide are irradiated with the maximum dose of X-rays, all the compounds in Fig. 4 are formed, but from methionine sulphone only homocysteic acid, aspartic acid, serine and alanine are formed. This degradation pattern can be explained by assuming that the reaction methionine $\rightleftharpoons$ methionine sulphoxide is reversible under the experimental conditions, but that methionine sulphone undergoes oxidative degradation only (Fig. 4). In this connexion it is of interest that methionine sulphoximine and methionine sulphoxide are degraded in similar ways. Obviously one of the first irradiation reactions of methionine sulphoximine is the splitting off of the NH-group. The further degradation products are not given in Fig. 4.

The investigation of the de-amination and decarboxylation processes will be the subject of further studies.

INHIBITION AND EXCITATION DUE TO GAMMA-AMINOBUTYRIC ACID IN THE CENTRAL NERVOUS SYSTEM

By Prof. TAKASHI HAYASHI

Department of Physiology, School of Medicine, Keio University, Tokyo

In 1954, Florey reported the presence in the mammalian brain and spinal cord of a factor, Factor I, which inhibits the generation of impulses by stretch receptor neurones of the crayfish[1], and in 1956 Elliott and Florey[2] purified the factor and identified it as γ-aminobutyric acid. In 1956, I suggested that β-hydroxy-γ-aminobutyric acid was the chemical transmitter of inhibition in the mammalian brain[3,4]. In 1957, McLennan showed that both these substances had an inhibitory action in nervous tissue[5].

The presence of γ-aminobutyric acid in the brain was discovered in 1950 by several workers[6,7], but the presence of β-hydroxy-γ-aminobutyric acid has not yet been conclusively demonstrated (my proof was indirect[8]) and most workers believe that γ-aminobutyric acid is the real inhibitory principle in the brain. However, I believe that stress should be laid on the importance of β-hydroxy-γ-aminobutyric acid for the following two reasons.

(1) It has a stronger inhibitory action than γ-aminobutyric acid on cerebral activity, for example, on the generalized seizure following electrical stimulation of the motor cortex in dogs. Most workers have experimented with stretch receptors and the spinal reflex and central electrical activity of lower animals[1,2,5], not on the activity of higher animals.

(2) In contrast to γ-amino-β-hydroxybutyric acid, γ-aminobutyric acid had an inhibitory as well as an excitatory action in some conditions.

The present results suggest that γ-aminobutyric acid is the precursor of both β-hydroxy-γ-aminobutyric acid and the substance causing excitation, of which the chemical constitution is not yet clear, but it appears to be a methylated derivative of γ-aminobutyric acid.

When electrical stimulation was applied to the motor cortex of the exposed brain of dogs, the generalized seizure appeared and continued for 60–180 sec. If, after the beginning of the seizure, a small dose of β-hydroxy-γ-aminobutyric acid or γ-aminobutyric acid, at an appropriate concentration, was rapidly introduced into the carotid artery, the seizure was abolished within 5–15 sec. If either substance was introduced into the cerebrospinal space, the seizure was abolished within 15–25 sec. Presumably these substances rapidly cross the blood-brain barrier and cerebrospinal fluid-brain barrier. It was confirmed that when isotonic saline solution, Ringer's solution or cerebrospinal fluid from other dogs was introduced in amounts up to 10–15 ml. no motor effect occurred.

When metrazole and sodium glutamate were introduced into the ventricle of dogs, they produced generalized seizure (Table 1). The latent periods did not exceed 15–20 sec. In contrast, *iso*nicotinic acid hydrazide and toxopyrimidine[9] had a latent period 30–200 times longer. To our surprise, vitamin B$_1$ and folic acid both produced the seizure and belonged to the group with the longer latent period.

Table 1. LATENT PERIODS TO PRODUCE SEIZURE VIA CEREBROSPINAL FLUID IN DOGS. 1 ML. SOLUTION WAS USED IN EACH CASE

Substance	Concentration (per cent)	Seizure	Latent period (sec.)
Metrazole	1·0	+	10–20
Sodium glutamate	10·0	+	15–20
*iso*Nicotinic acid hydrazide	20·0	+	2,000–2,400
Toxopyrimidine	10·0	+	600–1,200
Vitamin B_1	8·0	+	420–1,800
Folic acid	0·2	+	600–1,200

The most obvious interpretation of these results is that the convulsants with shorter latent periods act directly, by virtue of their chemical structure, and that the convulsants with the longer latent periods act indirectly. For example, they could undergo metabolic transformation during this longer period. Alternatively, it is possible that these compounds accelerate the production of the immediate excitatory mediator, or inhibit the production of compounds antagonistic to the natural mediator. In any event, the convulsants of the second group do not appear to be active *per se*. From these considerations, toxopyrimidine and *iso*nicotinic acid hydrazide are both antagonists of vitamin B_6, the coenzyme of glutamic decarboxylase. There have been many reports of the occurrence of seizure in animals suffering from vitamin B_6 deficiency. This can be interpreted as the result of β-hydroxy-γ-aminobutyric acid deficiency, the real inhibitory substance. This has led us to make a trial to establish a new experimental method as follows.

The method was to introduce γ-aminobutyric acid into the cerebrospinal fluid of dogs together with substances to change it into some unknown factor which would produce the generalized seizure[10]. In the experiment in Table 2, vitamin B_{12} was used instead of folic acid ; this had no effect by itself, but when combined with γ-aminobutyric acid and adenosine triphosphate, caused a seizure.

The preparation of adenosine triphosphate used was the sodium salt. The convulsant effect of sodium itself was considered. Sodium pyrophosphate is a strong convulsant when applied directly to the motor cortex of higher animals, or into cerebrospinal fluid, and its action has often been confused with that of adenosine triphosphate and that of pyrophosphate. Table 2 shows that the action of adenosine triphosphate must be due to its capacity to provide energy.

Table 2. SEIZURE DUE TO γ-AMINOBUTYRIC ACID AND VITAMIN B_{12}. 1 ML. OF EACH SOLUTION WAS USED

Substances	Concentration administered into cerebrospinal fluid (per cent)	Generalized seizure	Remarks
γ-Aminobutyric acid	0·02	–	
Vitamin B_{12}	0·0002	–	
γ-Aminobutyric acid + vitamin B_{12}	0·2 + 0·0002	–	
γ-Aminobutyric acid + vitamin B_{12} + adenosine triphosphate	0·02 + 0·0002 + 0·002	+	Latent period, 12 min.
Adenosine triphosphate	0·002	–	
Adenosine triphosphate + vitamin B_{12}	0·002 + 0·0002	–	

Table 3. SEIZURE DUE TO γ-AMINOBUTYRIC ACID AND VITAMIN B_1. 1 ML. OF EACH SOLUTION WAS USED

Substance	Concentration introduced into cerebrospinal fluid (per cent)	Generalized seizure	Remarks
γ-Aminobutyric acid	0·02	–	
Vitamin B_1	0·002	–	
γ-Aminobutyric acid + vitamin B_1	0·02 + 0·002	+	Latent period, 10 min.
Vitamin B_1	0·8	+	Latent period, 12 min.

Table 4. SEIZURE DUE TO VITAMIN B_1 WITH THE SUBSTRATES. 1 ML. OF EACH SOLUTION WAS USED

Substance	Concentration introduced into cerebrospinal fluid (per cent)	Seizure	Remarks
Pyruvic acid	0·02	–	
Pyruvic acid + vitamin B_1	0·02 + 0·002	+	Latent period, 10–12 min.
Citric acid	0·02	–	
Citric acid + vitamin B_1	0·02 + 0·002	+	Latent period, 11–12 min.
Succinic acid	0·02	–	
Succinic acid + vitamin B_1	0·02 + 0·002	+	Latent period, 12 min.

As shown in Table 3, γ-aminobutyric acid with vitamin B_1 at an appropriate concentration produced seizures with latent periods of 10 min. That the action of vitamin B_1 in this case is related to the energy liberation is shown by Table 4, where pyruvic, citric and succinic acids with vitamin B_1 at a subcritical concentration produced a seizure. The most probable interpretation of these effects of vitamin B_1 would be the energy liberation promoted to synthesize the excitatory mediator ; in other words, the action of B_1 is indirect.

In the biochemical methods hitherto used to detect the enzymatic action of tissues *in vitro*, homogenates or slices of tissue are incubated with the substrate and the consumption of oxygen, output of carbon dioxide or the appearance of the expected substances is measured. My new neurochemical method takes a seizure as an indicator. This is produced by substances added to the cerebrospinal fluid as substrates, coenzymes or energy liberators. Quantitative measurements can also be made by this method. Using it we obtained the following results.

(1) γ-aminobutyric acid is converted in some conditions to the excitatory mediator by cerebral tissue. (2) The excitatory mediator of higher animals is produced from γ-aminobutyric acid as substrate, through methylation by coenzyme, vitamin B_{12} or folic acid. (3) The process of conversion of γ-aminobutyric acid into the excitatory mediator requires energy which is supplied by a reaction involving thiamine. (4) γ-Aminobutyric acid is the parent substance to both the inhibitory mediator β-hydroxy-γ-aminobutyric acid) and the excitatory principle, which is presumed to be some methylated derivative of γ-aminobutyric acid.

Origin of Tektites

In a recent communication[1], Dr. Kohman suggests that tektites are meteorites which originate in interstellar space and collide with the solar system. I should like to direct attention again to the various facts that must be explained by any acceptable postulated history of these objects. (1) Tektites have chemical compositions remarkably similar to those of the more acid sedimentary rocks. This is true for the major and minor constituents. (I have been privileged to see analyses as yet unpublished on these minor constituents.) Such a chemical composition is not produced by any other naturally occurring chemical processes that we know of, except perhaps in very rare and special circumstances. (2) Tektites obviously have been melted, and this means that a temperature of some 1,500° C. or more was supplied by some means. In fact some appear to have been reheated to the melting point by passage through gas or by a blast of gas over the object. No terrestrial source of heat is known which could produce such high temperatures. (3) They are distributed thinly over areas of hundreds and thousands of kilometres in linear dimensions. (4) They are reported to contain aluminium-26 and beryllium-10. This observation is due to Dr. Kohman and Dr. Ehmann.

Dr. Kohman ignores items (1) and (2) above and gives us not the slightest indication as to how these objects could have accumulated, acquired their chemical composition and become melted in interstellar space. Apparently the problems that have concerned geochemists when a terrestrial origin is assumed become completely inconsequential when they are referred to the great cold vacuum far from the Sun. However, if items (1), (2) and (3) above could have been explained by non-miraculous means, neither Dr. Kohman, I, nor most of the readers of *Nature* would ever have heard of tektites.

Again I wish to direct attention to a suggestion I made last year[2], namely, that comet heads occasionally collide with the Earth, that such collisions would result in a flame-like mass of gas at a very high temperature capable of volatilizing the comet head and melting surface rocks of the Earth, and that high pressures capable of scattering bits of melted terrestrial materials over large areas would be developed. This was advanced in order to explain items (1), (2) and (3) above. The data of item (4) were not available at the time. It should be noted that Kohman and Ehmann's data required the lowest level counting technique that has been attempted and hence might well be checked by others, and that the terrestrial rocks used for comparison came from the glaciated area of Canada and an obsidian cliff in California, and hence they could scarcely have accumulated aluminium-26 and beryllium-10 from cosmic sources. Also, it may be that these elements could have been supplied from constituents of the comet head, though I am not particularly fond of this suggestion.

But comet heads should collide with the Earth from time to time. What effects should they produce? Would not something resembling the Alamagardo glass of the atomic bomb explosion be produced possibly or even probably? The energy of collision of a comet head with the Earth can reasonably be estimated as equivalent to some million or more atom bombs.

Number of Elastic Constants required in Crystal Elasticity

In recent years there have been several publications by Laval[1], LeCorre[2] and other authors[3-5] suggesting a more general approach to crystal elasticity, which, among other features, requires for a triclinic crystal 45 independent elastic constants instead of the classical 21 (with corresponding increases in each of the crystal classes). The stress tensor is not symmetrical, and body couples (or volume couples) act in the crystal.

We show in this communication that in those cases in which the Laval–LeCorre theory is applicable the number of independent elastic constants actually is 39 and not 45. This reduction is brought about by means of energy considerations and the following hypothesis.

Given a crystal subject to mechanical strains only, a necessary condition for the appearance of body couples in a certain element of volume is that a deformation should be present. (It is not stated that this condition is sufficient.)

In the strain–energy function

$$W = \tfrac{1}{2}\sum_{i,j=1}^{9} c_{ij}\varepsilon_i\varepsilon_j \qquad (1)$$

the following substitutions are introduced:

$$\left.\begin{aligned}
\varepsilon_4 &= \varepsilon_{23} = \varphi_1 - \theta_1\\
\varepsilon_7 &= \varepsilon_{32} = \varphi_1 + \theta_1\\
\varepsilon_5 &= \varepsilon_{31} = \varphi_2 - \theta_2\\
\varepsilon_8 &= \varepsilon_{13} = \varphi_2 + \theta_2\\
\varepsilon_6 &= \varepsilon_{12} = \varphi_3 - \theta_3\\
\varepsilon_9 &= \varepsilon_{21} = \varphi_3 + \theta_3
\end{aligned}\right\} \qquad (2)$$

The meaning of the new variables is the following: $2\varphi_\alpha$ is the pure shear deformation $\left(\frac{\partial u_\gamma}{\partial x_\beta} + \frac{\partial u_\beta}{\partial x_\gamma}\right)$ and θ_α is the pure rotation $\frac{1}{2}\left(\frac{\partial u_\gamma}{\partial x_\beta} - \frac{\partial u_\beta}{\partial x_\gamma}\right)$ around an axis parallel to X_α in every element of volume. If these new variables are introduced into equation (1), the energy density W becomes a function of the ε_α, φ_α and θ_α ($\alpha = 1, 2, 3$), and it can be separated into three parts:

$$W = W_d + W_{dr} + W_r \qquad (3)$$

W_d has terms that contain pure deformations only (ε_α and φ_α); W_r has terms that contain pure rotations only (θ_α); the terms of W_{dr} contain both deformations and rotations.

The strains ε_i ($i = 1, 2, \ldots 9$) and all the other elastic variables are functions of position and time; but consider a point in which at a given instant the strains are such that no pure deformation is present, that is, ε_1, ε_2, ε_3, φ_1, φ_2 and φ_3 all vanish. When this happens, the strain tensor is antisymmetric, and the element of volume has performed the rotation $\vec{\theta}\ (\theta_1, \theta_2, \theta_3)$. If this rotation is now increased by $\delta\vec{\theta}\ (\delta\theta_1, \delta\theta_2, \delta\theta_3)$, then the change δW in the energy density is equal to δW_r (the other two increments, δW_d and δW_{dr}, are in this case equal to zero). But according to the hypothesis stated above, there are no body-couples acting on this element of volume, the stress tensor is symmetric, and the moment per unit volume due to the couples exerted by the stresses is zero. It follows that the value of δW_r must be zero too. This requires that the coefficients of the six terms of W_r should vanish. This condition leads to the six following relations (details will be given elsewhere):

$$\left.\begin{aligned} 2c_{47} &= c_{44} + c_{77} \\ 2c_{58} &= c_{55} + c_{88} \\ 2c_{69} &= c_{66} + c_{99} \\ c_{45} + c_{78} &= c_{48} + c_{57} \\ c_{56} + c_{89} &= c_{59} + c_{68} \\ c_{46} + c_{79} &= c_{49} + c_{67} \end{aligned}\right\} \quad (4)$$

which, in the four-index notation, can be summarized in this general condition:

$$c_{\alpha\beta\gamma\delta} + c_{\beta\alpha\delta\gamma} = c_{\alpha\beta\delta\gamma} + c_{\beta\alpha\gamma\delta} \quad (5)$$

The analogue of (5) in the Voigt theory is:

$$c_{\alpha\beta\gamma\delta} = c_{\beta\alpha\delta\gamma} = c_{\alpha\beta\delta\gamma} = c_{\beta\alpha\gamma\delta} \quad (6)$$

which follows from the vanishing of the coefficients of both W_{dr} and W_r in (3).

The physical meaning of keeping the second term W_{dr} in (3) is the following: the local rotations θ_u may contribute to the strain–energy function if a deformation is also present. It would, of course, be unjustified to call this contribution W_{dr} an elastic energy in the case of a rigid rotation, but it is part of the elastic energy in dynamic cases such as the propagation of elastic waves in crystals. In other words, rotations of undeformed elements of volume keep the strain energy invariant.

The new conditions (4) reduce by six the number of independent elastic constants: from 45 to 39. It is interesting to notice that, except in the triclinic and monoclinic classes, the last three of those six conditions are already satisfied by the elastic constants of Laval and LeCorre.

We have applied the conditions (4) to the elastic constants tabulated by LeCorre[2] in his paper of 1953, and have obtained thus the new matrices for each of the 11 Laue groups and for isotropic solids. These matrices will be published elsewhere. Table 1 summarizes the number of independent elastic constants for each of those 12 cases. The headings *V*, *LL* and *JW* correspond to the matrices of Voigt, Laval–LeCorre and ours, respectively.

Table 1

Laue group	*V*	*LL*	*JW*
$\bar{1}$	21	45	39
2/*m*	13	25	21
mmm	9	15	12
$\bar{3}$	7	15	13
$\bar{3}$*m*	6	10	8
4/*m*	7	13	11
4/*mmm*	6	9	7
6/*m*	5	11	9
6/*mmm*	5	8	6
*m*3	3	5	4
*m*3*m*	3	4	3
Isotropic	2	3	2

It can be seen that there is no distinction now between the elastic constants of Voigt and the new ones for the last two cases: the Laue group *m*3*m* and isotropic solids.

As an example, ammonium dihydrogen phosphate (class $\bar{4}2m$; Laue group 4/*mmm*) may be mentioned. Its elastic constants, of which new measurements will soon be reported elsewhere, do not fit into the Voigt matrix, but can be satisfactorily interpreted both with the matrix of Laval and LeCorre and the one suggested by us. It is interesting to note, however, that, while not all the nine elastic constants of Laval and LeCorre can be determined dynamically because the experiments only give the 7 values of c_{11}, c_{33}, c_{44}, c_{55}, c_{66}, $c_{12} + c_{69}$ and $c_{13} + c_{47}$, our conditions (4) reduce in this case to:

$$\left.\begin{aligned} 2c_{47} &= c_{44} + c_{55} \\ c_{69} &= c_{66} \end{aligned}\right\} \quad (7)$$

as a result of which the number of independent elastic constants is reduced from 9 to 7, and all of them can be determined by dynamic methods.

Effects of Pressure on some Optical and Electrical Properties of Diamonds

It has frequently been remarked[1] that although diamond crystals which are very efficient as conduction counters of ionizing radiations are usually free from birefringence, there is no strong correlation between counting efficiency and the degree of birefringence of counting crystals of average performance. Conversely, it may be inferred that the performance of diamonds as crystal counters will be almost independent of pressure at pressures which produce considerable artificial birefringence, and the following experiments have confirmed this supposition.

Satisfactory counting crystals were placed between two hardened steel electrodes which could be screwed together to apply pressures up to 10^4 atm. The pulse-counting technique could not be used directly as it proved impossible to separate the effect due to change in electrode capacity. However, the total β-ray bombardment current was observed and no significant change could be detected.

An alternative method of examining the effect of pressure on the width of the energy gap between the top of the valence band and the bottom of the conduction band is from measurement of the ultra-violet absorption cut-off wave-length. Using a spectrometer capable of resolving 1 A., no change in the cut-off wave-length was observed nor was there any alteration in the position of characteristic absorption bands at 2359 A. and 2363 A. As present theory indicates a change of only 10^{-8} eV. atm.$^{-1}$ in the width of the energy gap, these negative experimental results are consistent with theory.

Measurements of the Permeability Tensor for 'Ferroxcube' at 24,000 Mc./s.

It is well known that ferrimagnetic materials become anisotropic upon application of a magnetic field and that consequently the permeability of a magnetically saturated ferrite medium is described by a tensor[1]:

$$\|\mu\| = \begin{Vmatrix} \mu & -jk & 0 \\ jk & \mu & 0 \\ 0 & 0 & 1 \end{Vmatrix}$$

For a positive and negative circularly polarized wave, the tensor is diagonalized, and the effective permeability is a scalar, $\mu \pm k$. The real and the imaginary parts of the elements of the tensor have been measured by several workers[2,3], using resonance cavities excited with circularly polarized modes. In order to study ferrite itself, it was pointed out by Spencer *et al.*[3] that it is necessary to determine the intrinsic magnetic quantities μ and k. Because of the radiofrequency demagnetizing fields the values $\tilde{\mu}$ and $\tilde{k}$ derived from the measurements depend on the sample shape. Those intrinsic values are computed from the experimental values using a magnetostatic approximation for the internal field.

Practically all measurements published hitherto have been carried out at 3,000 Mc./s. or 10,000 Mc./s.; most of them on American commercial products. We have measured the tensor components for the European commercial product 'Ferroxcube IV *B*' at 24,000 Mc./s. It is interesting to consider the position of μ at our working frequency on the dispersion and the absorption curves for the initial permeability. These dispersion and absorption curves can be interpreted[4] as a natural ferromagnetic resonance in the internal anisotropy field. 24,000 Mc./s. is situated beyond the anomaly of the dispersion curve. As a consequence, the residual magnetic losses are much smaller.

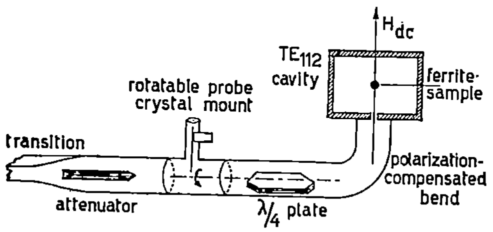

Fig. 1. Diagram of the circular polarizing device

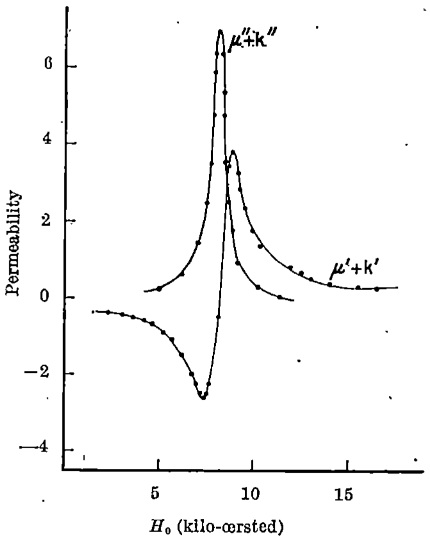

Fig. 2

In our measurements we have used a TE_{112}-reflexion cavity with ferrite spheres or disks placed in a position of maximum radio-frequency magnetic field and zero radio-frequency electric field. In order to excite the cavity, microwave radiation is fed through a circular polarizing apparatus constructed at our laboratory and shown schematically in Fig. 1. The sense of the circular polarization is reversed either by changing the orientation of the λ/4-plate or by reversing the d.-c. magnetic field. Care has been taken to avoid ellipticity in the circular guide and also on the adjustment of the quarter-wave plate.

The empty cavity resonates at 23,995 Mc./s. with a loaded Q-value of 3,985. Using the Bethe–Schwinger cavity perturbation theory, it is easily shown that the frequency shift, and the change in loaded Q, are directly proportional respectively to the real $(\tilde{\mu}' \pm \tilde{k}')$ and the imaginary part $(\tilde{\mu}'' \pm \tilde{k}'')$ of the effective permeability. For a sphere the intrinsic values are related to the experimental values by the equation:

$$\mu \pm k = -[2(\tilde{\mu} \pm \tilde{k}) + 1][\tilde{\mu} \pm \tilde{k} - 4]$$

The results of a typical run on a polycrystalline sphere with diameter 0·95 mm., using the apparatus described, are shown in Fig. 2. The values $\mu' + k'$ and $\mu'' + k''$ are plotted against the steady magnetic field. From other measurements on spheres and disks and with the aid of Kittel's relations for ferromagnetic resonance[5], we were able to calculate an effective value of g. We found a mean value of 2·11.

Further details will be published later.

Anomalous Attenuation in Linear Electron Accelerators

WHILE operating the linear electron accelerator at the University of Ghent, interesting phenomena, similar to those reported on some accelerators in England[1-4], were observed. These phenomena have been explained on the basis of the multipactor effect[3].

Miller and Saxon[2] measured in a linear accelerator an attenuation of 2·5 db. for all power-levels, in the absence of the magnetic focusing field. In the presence of such fields, the attenuation was still found to be of the order of 2·5 db. for power fluxes of a few milliwatts and several megawatts. There was, however, a variation of attenuation with power in an intermediate range. They noted a maximum of 12 db. for an input power of 250 kW. If the power-level is increased, the attenuation falls, approaching 2·5 db. for an input of 3 MW. We consider that no satisfactory explanation has yet been given of the dependence of attenuation on power-level.

Considering a condenser-type field $E\sin(\omega t + \varphi)$ and using the same notation as Mullett, Clay and Hadden[3], the conditions for stable multipactoring are:

$$\mathrm{d} = \frac{e}{m} \cdot \frac{E}{\omega^2}\left[(2n + 1)\pi\cos\varphi + 2\sin\varphi\right]$$

and

$$0 < tg\,\varphi < 2/\pi\,(2n + 1)$$

where n is an integer. This leads to the fact that for each n the multipactor effect can occur in a stable way only between two limiting values, E_1 and E_2, of E. These intervals (E_1, E_2) are rather narrow. With increasing n, they become smaller and smaller, the fields needed decrease and the energy ε with which the electrons can arrive at the opposite plate decreases also. The electric field E, parallel with the axis of the accelerator, is for $a \leqslant r \leqslant b$ (b, radius of corrugations; a, radius of iris-hole) given by an expression containing Bessel functions. It turns out that this function can (at least for those parameters used for accelerators) be approximated rather well by a decreasing linear function of r:

$$E = \beta(b - r) \qquad (\beta > 0)$$

For a given value of n, the multipactor effect can occur only within a ring the radii of which, r_1 and r_2, are defined by E_1 and E_2. These rings are very narrow, especially for $n \neq 0$.

The area S of a ring is given by:

$$S = \begin{cases} 0 & \text{for } (b-a)\beta \leqslant E_2 \\ \pi\left[\left(\dfrac{E_2}{\beta} - b\right)^2 - a^2\right] & \text{for } E_2 \leqslant \beta(b-a) \leqslant E_1 \\ \pi\left[\left(\dfrac{E_2}{\beta} - b\right)^2 - \left(\dfrac{E_1}{\beta} - b\right)^2\right] & \text{for } E_1 \leqslant \beta\,(b-a) \end{cases}$$

S is maximum for $\beta = (E_1 + E_2)/b$. It is obvious that (for any particular value of n) S is directly proportional to the loss of energy. The fact that the anomalous attenuation is measured only in the presence of the focusing field can be explained satisfactorily. In the corrugations, there is not only an electric field E_2, but also a component H_θ, causing a radial force on the electrons which pushes them away from the regions where stable multipactoring is possible. The axial magnetic focusing field tends to prevent electrons from moving out of these regions. If the power flux through the accelerator is increased, the values of E_1 and E_2 are unchanged. The interval of r (r_1, r_2) where the effect can occur moves, however, toward the outside and falls off (Fig. 1).

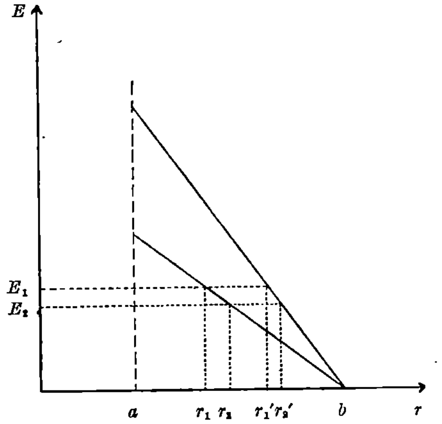

Fig. 1

For very low power-input, only high-n rings could occur. However, the effect will not be observed, because ε is so low that $\eta < 1$ (η, secondary emission coefficient). For very high power input, the lowest values of n could be reached, but then also the effect will not be produced, ε being so high that $\eta < 1$. Because of the larger area involved and the larger value of ε, the greater part of the loss of energy must be due to the inner ring that is possible in any particular case. In the experiment by Miller and Saxon, there was an attenuation of 10 db. for an input power of 250 kW. Taking into account only the ring corresponding to the lowest value of n, and supposing that there is only one cavity, one finds this attenuation for $\beta = (E_1 + E_2)/b$ for which $S = \pi b^2(E_1 + E_2)/(E_1 + E_2)$. This leads to an attenuation of 0·157 db. for an input power of 3 MW. Considering an accelerator with no other losses than those due to multipactoring, one comes somewhat nearer to reality. Then β is a function of z (co-ordinate along the axis). If the machine has a purely periodic structure, one can write:

$$\mathrm{d}P \sim \beta\mathrm{d}\beta = -C'S\mathrm{d}z \qquad (C' = \text{constant})$$

Using the third expression for S, this leads to

$$z = \frac{1}{2bC}\left[\frac{\beta^3(0) - \beta^3}{3} + \frac{E_1+E_2}{4b}\{\beta^2(0)-\beta^2\} + \frac{(E_1+E_2)^2}{4b^2}\{\beta(0)-\beta\} + \frac{(E_1+E_2)^3}{8b^3}\ln\frac{\beta(0) - (E_1+E_2)/2b}{\beta - (E_1 + E_2)/2b}\right]$$

$$(C = \text{constant})$$

Maximum attenuation will occur approximately for $\beta(l) = 3\;(E_1 + E_2)/4b$ (l, length of the accelerator) and in the considered case one finds 0·22 db. for an input power of 3 mW. This agrees well with the experiment.

We want to point out that even if the absolute losses of power were constant for different power-levels, we would find a low attenuation (0·34 db.) for 3 MW. if one assumed 10 db. for 250 kW. input.

Finally, it is interesting that the increase of the input power will also increase the radial forces which try to push the electrons away from the stable region, while E remains constant in the ring considered. This will decrease the losses due to the multipactor effect even more.

We wish to thank the Inter-University Institute for Nuclear Sciences (Belgium), which sponsored this work.

A New Method of measuring Susceptibility

In recent years simple detectors of weak magnetic fields have become available. Magnetometers using the Hall effect in indium antimonide[1] or ferrite saturation[2] are capable of measuring fields of a small fraction of an œrsted, and they may be used in a magnetic circuit as detectors of magnetic flux, being analogous to a galvanometer detecting current in an electric circuit.

Using this principle, we have built the magnetic analogue of a Wheatstone bridge, with a permanent magnet as the source of magnetomotive force (Fig. 1). The magnetic detector (D) will register no flux when the reluctances of the four air gaps in the soft iron bridge circuit are equal, since the magnetic potentials at A and B will then be the same. If the reluctance of one gap is changed by inserting a sample with a permeability different from that of air, the bridge will become unbalanced and the detector will indicate the magnetic flux passing through it. The bridge may be initially balanced by moving a ferromagnetic screw in one of the gaps.

With gaps of 5-mm. length and $0 \cdot 5$-cm.^{2} cross-sectional area, and an *M*2021 Mullard 'Ticonal' magnet, a field of 1,500 œrsted is obtained in each gap. An InSb magnetometer unit, used in conjunction with a transistor oscillator and amplifier, can detect a field of 10^{-4} œrsted (Hilsum, C., and Thompson, N. A. C., unpublished work). Ideally, therefore, it should be possible to detect a departure from unit permeability by about one part in 10^7, that is, a susceptibility of 10^{-8} c.g.s. units.

The performance of an actual instrument is illustrated in Fig. 2. Measurements were made on aqueous solutions of nickel chloride the susceptibilities of which were calculated from the formula given by Nettleton and Sugden[3]. The calibration is essentially linear, and the instrument is quite capable of measuring diamagnetic susceptibilities such as that of de-ionized water. Our apparatus consists of two small boxes, about 8-in. cube, one of mumetal containing the bridge, and the other for the display meter and the electronics, which operate from a small internal dry battery.

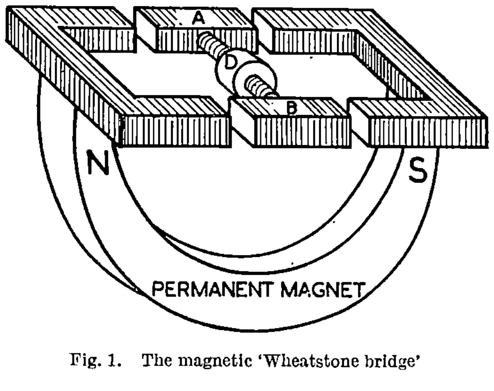

Fig. 1. The magnetic 'Wheatstone bridge'

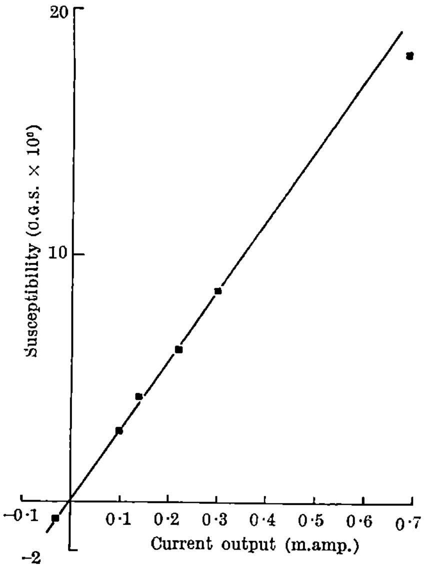

Fig. 2. Calibration curve of susceptibility meter

The instrument has the advantages over the usual susceptibility balance of being portable, unaffected by vibration and needing no external power supplies. It is, however, sensitive to variations in the local magnetic field, and measurements cannot be made while ferromagnetic objects are being moved near it. We have found the instrument to be very convenient for use both in the laboratory and in the open. A more detailed account will be given elsewhere.

We are grateful to the Admiralty for permission to publish this communication.

Helium in Natural Gas in the Witwatersrand

During a visit to the Union of South Africa in the spring of 1957 I observed escapes of natural gas associated with faults and fissures in the underground workings of some of the gold–uranium mines of the Witwatersrand.

It seemed likely that as these major structures cut the uranium-bearing conglomerate horizons, the gas might contain appreciable quantities of helium. Arrangements were therefore made with Dr. J. J. Marais of the Anglo-Transvaal Consolidated Investment Co., Ltd., for a sample of gas to be collected from the Virginia Mine. This material has been analysed chemically and by mass-spectrometry. The results are shown in Table 1.

The high content of helium is of particular interest as the study of its distribution is likely to throw new

Table 1

	Chemical analysis	Mass-spectrometric analysis
Methane	78·4	76·6
Nitrogen	12·1 (by difference)	13·9
Helium	8·0	8·3
Hydrogen	0·1	0·1
Oxygen	0·1	0·2
Argon	0·3	0·5
Carbon dioxide	0·8	0·4
Carbon monoxide	0·2	—

light on the origin of the mineralization of the Witwatersrand System.

It is not known what volume of gas is available, but it would seem from present information that this field merits further study as a possible commercial source of helium.

I wish to thank the Director of the Geological Survey of Great Britain for permission to publish this communication, the Government Laboratory, London, for carrying out the chemical analysis, and the Mass-Spectrometer Group, Atomic Energy Research Establishment, Harwell, for carrying out the mass-spectrometric analysis.

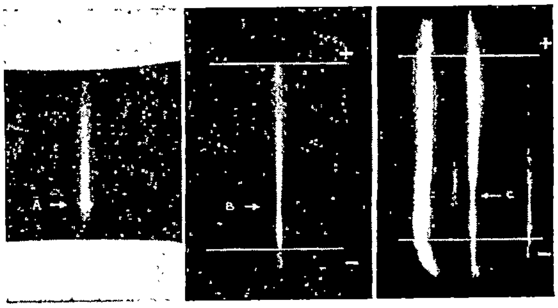
Observations on Overvolted Uniform Field Spark Gaps

The pre-breakdown processes occurring in a uniform field gap before a visible discharge takes place have been described by Townsend as the cumulative growth of ionization by successive generations of avalanches. The collision processes are mainly of the type defined by the ionization coefficient α. The criterion usually accepted as setting minimum breakdown voltage for a gap d is that $\gamma \exp(\alpha d) = 1$ where α and γ are the coefficients for the production of secondary electrons. If a spark gap has a voltage applied to it which is in excess of this minimum value then the avalanche growth mechanism will be similar, but the amount of space charge in one avalanche will be greater as it crosses the gap. If the voltage is sufficiently high, one avalanche can produce such a density of positive charge in its head that a 'streamer' or luminous filamentary channel will bridge the gap from the avalanche head. Depending on the voltage, this point from which the streamer growth starts can occur at almost any position across the gap. Meek[1] and Raether[2] gave the empirical relation $\alpha x_{cr} = 20$ for the critical avalanche-length x_{cr}.

Such a mechanism of growth has been observed in recent work with overvolted gaps using pulses of 0·1 μsec. duration applied to 2-cm. gaps in air at a p.d. of 800 mm.cm. Fig. 1*a* shows a typical cloud-chamber photograph of the charge distribution as the result of one avalanche attaining critical multiplication and forming anode- and cathode-directed streamers. This photograph clearly shows the avalanche head as a small cloud of ionization with the two filamentary discharges bridging the gap from the head to the anode and cathode respectively. If the voltage had been maintained for a sufficiently long period the external circuit would have discharged through these highly conducting columns.



(*a*) (*b*) (*c*)

Fig. 1 (*a*), Cloud-chamber photograph of streamer showing avalanche head at *A*. (*b*), Photograph of the light from a streamer showing constriction at *B*. (*c*), Photograph of the light emitted from several streamers. One shows a sphere in the constriction at *C*

Fig. 1*b* is a photograph of the light emitted from these streamers taken under similar conditions as Fig. 1*a* but without expansion of the cloud chamber. It can be seen that a constriction or 'neck' occurs at a point corresponding to the head of the avalanche in the cloud-chamber photograph. This suggests that the streamer has started from the avalanche head and widened out as it reaches the anode and the cathode. For longer pulses which allow the later stages to develop, photographs show that a filamentary discharge is formed, and its tortuous path is always contained within the existing streamer region.

If the discharge current increases above a certain value then emission of light increases within the constriction appearing as a small circle with the avalanche head as centre, see Fig. 1*c*. To an observer these points appear as bright beads of light much more intense than the remainder of the discharge. A fuller account of this work is to be published elsewhere.

Diffraction of Light by Ultrasonic Waves—Oblique Incidences

Various expressions have been obtained by several workers for the diffraction of light by ultrasonic waves[1] based essentially on the propagation of electromagnetic waves through a stratified medium. These expressions, being non-convergent, are limited in their scope and application[2]. Aggarwal[3] has given expressions for the intensity of different diffraction orders in a closed form which gives definite results under various experimental conditions. One such condition states that for low sound intensities in the medium, instead of the usual single maximum attained by the first three orders at their respective Bragg reflexion angles, $\alpha/2$, α and $3\alpha/2$, there are one, three and five reflexion maxima for the three orders respectively.

In order to verify this significant result we set up the usual diffraction apparatus of Debye and Sears and of Lucas and Biquard. The ultrasonic intensity was kept very low. The intensities of the diffracted orders were measured by means of a photomultiplier tube and read off on a scale, for successive small tilts of the quartz crystal from the normal incidence of the sound beam to light path. These angles of tilt were measured accurately by an optical lever system. We used ethyl iodide as the liquid medium giving sound of wave-length 0·0041 cm. at a frequency of 21·05 Mc. For the third-order reflexions, however, n-hexane was substituted giving sound waves of 0·0051 cm. at the same frequency.

The results for the first, second and third order of the diffraction pattern on one side are given in terms of the Bragg angle in Fig. 1. Here $\alpha/2$ is the reflexion maximum for the first order.

The first order shows a maximum at $\alpha/2$ only, while the maxima at $\alpha/2$, α and $3\alpha/2$ for the second order are unmistakably clear. $\alpha/2$, α, $3\alpha/2$ and 2α are the peaks for the third order line, but perhaps due to the low sound intensity and greater tilt of the quartz crystal the fifth one at $5\alpha/2$ does not make its appearance markedly. However, these results are in good agreement with Aggarwal's expressions.

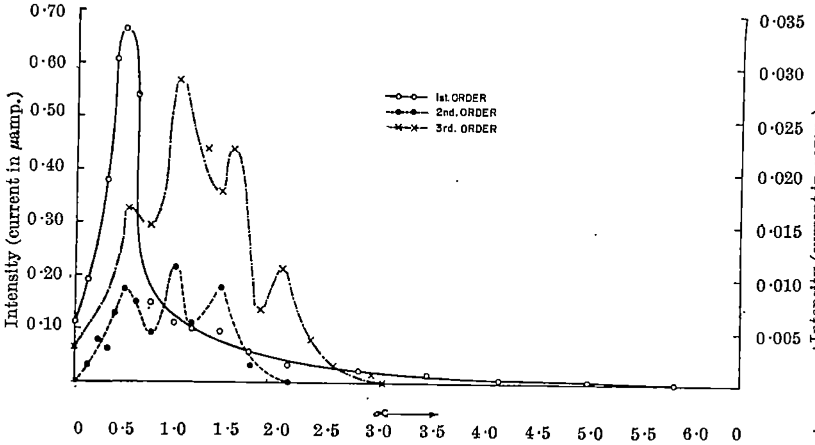

Fig. 1. The abscissa represents the reflexion angle α, and the ordinate (left-hand side for the first order and the right-hand side for the second and third orders) represents the intensity expressed in terms of the current in microamperes

It is of interest that a careful study of the photograph published by one of us[4] also shows the presence of more than one maximum for the second order.

Full details will be published elsewhere in due course.

Uptake of Molecular Oxygen by Ferrous Complexes

During the course of a deliberate study of models for iron porphyrin complexes of biological importance we have shown that ferrous dimethylglyoxime, $Fe(DMG)_2$, is capable of combining reversibly with molecular oxygen. The reaction occurs in a mixed solvent, 50 per cent aqueous dioxan, in which the complex is appreciably soluble in the presence of various added bases such as pyridine, ammonia, histidine and imidazole. The pH of the solution must be in the range 7–11 if the reaction is to be observed. We consider the reversible reaction to be

$$Fe(DMG)_2(base)_2 + O_2 \rightleftharpoons Fe(DMG)_2(base)\,O_2 + base$$

The forward reaction can be followed by the changes in absorption spectrum as oxygen is bubbled through the solution of the $Fe(DMG)_2(base)_2$ complex and the back reaction can be followed by observing similar changes bubbling pure nitrogen through a solution of the oxygenated complex. The spectrophotometric measurements show that the reaction is completely reversible for some of the complexes but that some autoxidation occurs with others. The changes in absorption spectrum with uptake of oxygen are very similar to those which occur on the uptake of carbon monoxide or cyanide by the complex. Both the liberation of oxygen and the liberation of carbon monoxide from the complexes have been studied manometrically. There would appear to be two complexes in one of which two molecules of oxygen or carbon monoxide are bound to the cation and, in the other, one molecule is bound as in the above equation. Comparison of the manometric and spectrophotometric measurements indicates that the first molecule of oxygen or carbon monoxide is picked up slowly but the second molecule is picked up so very slowly that the two stages of the reaction can be followed.

The rate at which oxygen replaces a base molecule in the above equation is sensitive to the base, as is the rate at which the oxygen molecule can be discharged afterwards. Oxygen is picked up most rapidly by the histidine complex and least rapidly by the pyridine complex. The evolution of oxygen is least rapid in the case of the pyridine complex.

Clearly these complexes parallel the behaviour of different biological complexes some of which pick up oxygen, some of which are autoxidizable and some of which are almost inert to oxygen. We hope to publish a detailed account of our observations together with a correlation between the properties of the models and the properties of the biologically important compounds shortly.

Entropy Production in Irreversible Mechanical Processes

In discussing the concept of entropy, many authors relate the 'production of heat' or 'energetic heat evolution' ($\mathrm{d}Q_{\text{irrev.}}$) accompanying an irreversible process to the 'loss of useful work' and to the 'irreversible production of entropy' (d_iS) by an equation of the form[1]:

$$\mathrm{d}Q_{\text{irrev.}} = \mathrm{d}W_{\text{irrev.}} - \mathrm{d}W_{\text{rev.}} = T\mathrm{d}_iS \qquad (1)$$

where $\mathrm{d}W_{\text{rev.}}$ and $\mathrm{d}W_{\text{irrev.}}$ are, respectively, the amounts of work received by the system during a reversible and an irreversible change between the same initial and final states of the system; T is the absolute temperature of the system, supposed uniform throughout.

Now in an irreversible mechanical process, such, for example, as the impact of a hammer on a nail, or a frictional process, we observe a rise in temperature in the immediate neighbourhood of the process. Equation (1) cannot be applied until the temperature has been equalized—presuming always that the heat capacity of the surroundings is so large that no change in their temperature is observed. A question which then arises (particularly in the minds of students being introduced to these ideas) is whether it is possible to describe the system thermodynamically in the interval before the re-establishment of thermal equilibrium. The following outlines a way in which this may be done.

Consider, as an example, the impact of a body having a kinetic energy E, with a fixed anvil to which it becomes fused on impact. Suppose that the total heat capacity of body plus anvil (which together form 'the system') is C, and that after impact they are thermally isolated from the surroundings. If body, anvil and surroundings were at a temperature T_0 before impact, the system will have a temperature T_1 after impact, where

$$T_1 - T_0 = E/C \qquad (2)$$

An amount of mechanical energy E has disappeared, but now that the system is at a higher temperature than the surroundings it can act as a source of thermal energy to operate a reversible heat engine operating between T_1 and T_0. Action of the engine will lower the temperature of the system until it reaches T_0 again; this reversible reduction in T_1 to T_0 is accompanied by the performance of mechanical work by the heat engine.

Thus at the conclusion of the impact process, although mechanical energy E has disappeared, it is not all irrevocably 'lost' since some can be recovered by the use of a heat engine. It is readily shown that if in each cycle the heat engine removes an infinitesimal amount of heat from the system, then in lowering the temperature of the system from T_1 to T_0 (in an infinite number of cycles) an amount of work (W) can be recovered, given by:

$$\frac{W}{E} = 1 - \frac{T_0}{T_1 - T_0} \ln \frac{T_1}{T_0} \qquad (3)$$

The fractional dissipation of energy in the impact considered is thus equal to the second term on the right-hand side of (3). Formally, two limiting cases may be envisaged. First, if $E/C \rightarrow \infty$, $T_1 \rightarrow \infty$ and $W \rightarrow E$. Thus if 'the system' were infinitesimally small ($C \rightarrow 0$), all the kinetic energy could be regained as mechanical work from the heat engine. Alternatively, if $C \rightarrow \infty$, $E/C \rightarrow 0$, $T_1 \rightarrow T_0$, and $W \rightarrow 0$, the whole of the energy is dissipated.

This formal analysis is, however, subject to the limitation of all thermodynamic arguments, namely, that it must be restricted to assemblies of molecules large enough for statistical averages to have a physical meaning. Thus the primary process in an impact is the sharing of kinetic energy between the surface atoms of the two bodies over the area of impact. The motion imparted to them is an ordered motion, so that for the first 10^{-14} to 10^{-12} sec. after impact the 'temperature' of the surface atoms cannot be defined. This becomes possible only after sufficient vibrations have occurred to share this energy randomly among a sufficient number of molecules. What the present argument shows is that even when this randomization has occurred, only part of the mechanical energy has been rendered 'useless', the rest being recoverable, in principle, if temperature equalization with the surroundings is achieved through the medium of a reversible heat engine. If the initial rise in temperature is associated with a small part of the system, the major part of the 'irreversibility' of a mechanical process is to be associated not with the mechanical act itself but with the subsequent spontaneous flow of heat from the site of the action in the processes leading first to thermal equilibrium within the system and then to temperature equalization with the surroundings.

The subdivision of the total irreversibility will depend on the process considered. For example, in a collision between 'perfectly elastic bodies' the ordered motion is maintained as elastic waves which are reflected from the boundaries of the bodies and return to the point of impact to give rise to the 'restitutional force' which restores to the bodies the whole of the kinetic energy. The imperfection of real impacts presumably arises from the scattering of these waves throughout the bodies, possibly accompanied by some randomization near the site of impact. In a completely inelastic collision, the randomization may occur within a few molecular diameters of the surface with a large local temperature rise.

Essentially similar reasoning can be applied to the irreversible flow of an electric current through a conductor, and to spontaneous chemical reactions: the entropy production is associated to a major extent with the process of temperature equalization after the cessation of the primary phenomenon.

Surface Oxide Films and the Breakaway Corrosion of Uranium

During corrosion, the more reactive metals, for example, aluminium, zirconium, titanium and uranium, usually form a protective oxide film which reduces the corrosion-rate to a low value. Recently, it has been observed that this low corrosion-rate can increase suddenly and the phenomenon has been termed 'breakaway'. The cause of breakaway has not been finally established, but it appears that the effect is associated with a change in the protective oxide film.

Surface oxide films have been studied by many methods, one of which is to consider the oxide layer as the dielectric of an electrolytic condenser[1], the underlying metal forming one electrode and the corrosive liquid the other. By measuring the electrical capacity and leakage resistance of such a condenser, some estimate of the thickness and conductivity of the oxide can be made.

Wanklyn[2] has commented on the limitations of capacity measurements as a means of estimating oxide thicknesses when applied to the problem of breakaway corrosion of zirconium. In view of this it may be of interest to report some results recently obtained while applying a related method to the study of breakaway corrosion in uranium–water systems.

The experimental techniques, which will be reported in full elsewhere, permitted measurements to be made without disturbing the corrosion process, the results being expressed as the capacity and resistance of an analogue circuit consisting of a condenser and resistance in parallel.

Earlier work[3,4] has shown that the presence of hydrogen in solution in γ-uranium alloys is associated with an increase in corrosion-rate of about × 20. To study this effect measurements were made of the capacity and resistance of the oxide films on the surface of specimens which were free of hydrogen and on specimens into which hydrogen had been introduced, prior to the corrosion test, by cathodic charging.

The results show that the thickness of the films, as indicated by the capacity, is not changed by the presence of hydrogen in solution in the metal. The measured capacities were the same to within ± 10 per cent for the hydrogen-charged and hydrogen-free samples. However, a marked increase in the conductivity of the oxide is associated with the presence of hydrogen in the metal. The resistance of the oxide on the hydrogen-free specimens was greater than 10^6 ohm/cm.^{2}, whereas that on the charged samples was of the order 3×10^5 ohms/cm.^{2}.

While there are no data available on the hydrogen content of the oxide layers, it may be expected that increasing hydrogen content of the metal would be accompanied by increasing hydrogen content of the oxide. The mechanism by which hydrogen or hydrogen ions produce this change in resistance is not clear as, under the conditions of the corrosion reaction, there is no possibility of hydrogen reducing the oxide.

This work, which is continuing, was sponsored by the U.S. Navy, Bureau of Ships.

Kinetics of the Thermal Dehydration of Kaolinite

For the decomposition of a solid substance, one of the products being volatile, the following equation relating the kinetic parameters of the reaction to the results of thermogravimetric analysis was recently derived by Freeman and Carroll[1]:

$$\frac{\frac{-E}{2\cdot 3R}\,\Delta\,(T^{-1})}{\Delta\log w_r} = -x + \frac{\Delta\log dw/dt}{\Delta\log w_r}$$

In this equation E represents the energy of activation, x the order of the reaction, w the loss in weight of reactant up to time, t, and $w_r = w \;\; - w$, where w_c = loss in weight at completion of the reaction. R is the gas constant and T the absolute temperature. A plot of $\frac{\Delta\log dw/dt}{\Delta\log w_r}$ vs. $\frac{\Delta(T^{-1})}{\Delta\log w_r}$ then results in a straight line from which the parameters x and E are easily derived. For the purpose of this plot w_r can be determined directly from the thermogram as well as the values of dw/dt, the rate of change of weight of sample with time, when the thermogravimetric analysis is conducted at a constant heating rate.

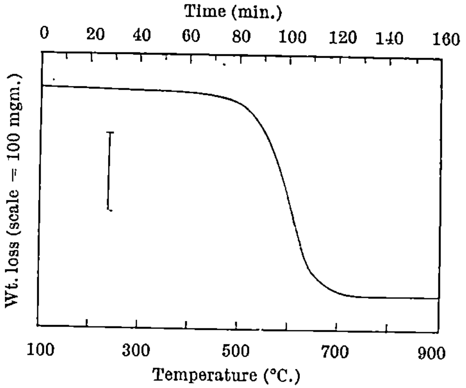

Fig. 1

The dehydration of kaolinite was studied as a function of the above equation. The sample consisted of the < 1μ fraction, separated by classical sedimentation and supercentrifuge techniques, from a commercially available kaolin (Whitehill pottery clay from Continental China Clay Co., Brussels). X-ray diffraction revealed a very pure monomineral composition in agreement with the results of chemical analysis, the figures in per cent of which are (after preliminary drying at 110° C.): loss on ignition (950° C.): 13·57; SiO_2: 46·76; Al_2O_3: 39·55; Fe_2O_3: 0·05; TiO_2: 0·05; CaO: 0·17; MgO: 0·02; Na_2O: 0·12; K_2O: 0·45. The thermogram, reproduced from 100° C. onwards in Fig. 1, was taken with a photographically recording Chevenard thermobalance (Société Adamel, Paris). The analysis was performed in air with a manually controlled constant heating rate of 5° per min. on a previously dried (150° C.) 2 gm. sample placed in a glazed porcelain crucible.

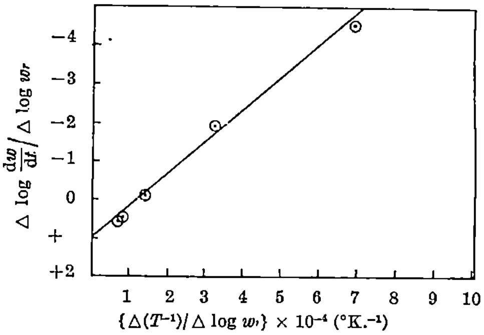

Fig. 2

Fig. 2 is a graph of $\frac{\Delta\log dw/dt}{\Delta\log w_r}$ vs. $\frac{\Delta(T^{-1})}{\Delta\log w_r}$. From this the following values for the order of reaction and the energy of activation are derived: $x = 1$ and $E \doteqdot 37\cdot 80$ kcal./mole.

Previously several authors, studying the kinetics of the dehydration of clay minerals by isothermal loss-in-weight measurements[2,3] and mathematical treatment of differential thermal analysis curves[4] (using Vold's method[5]), arrived at the same result with respect to the order of reaction. The values for the energy of activation calculated by these authors for kaolinite clays are respectively 44·00 (ref. 2), 44·83 (ref. 3) and 55·00 kcal./mole (ref. 4). The difference between the proposed value and the reported ones is to be allowed for by differences in composition and size of particles of the samples examined and by the different techniques involved (it is to be noted that the figures of refs. 3 and 4 apply to the same sample). With regard to the last factor the thermogravimetric method has a distinct advantage. In the isothermal method some dehydration may occur before the sample has reached the constant temperature of interest. The mathematical treatment of differential thermal analysis curves is concerned with the difficulty of correct choice of the transition point, and needs a correct determination of the heat capacity of the sample.

An Overhauser Effect in Natural Crude Oil

WE have discovered an Overhauser effect in natural crude oil. The phenomenon was detected in a 12-ml. sample of oil in an H_0 field of 18·5 gauss (ν_p = 80 kc./s.; ν_e = 52·6 Mc./s.).

The Overhauser interaction occurs between the dissolved asphaltene free radicals and the hydrogen protons in the lighter hydrocarbons of the surrounding fluid. The electron resonance of these free radicals in petroleum has been previously investigated by Gutowsky, Ray, Rutledge and Unterberger[1]. The asphaltenes might well be considered as comprising a very stable colloidal suspension rather than being in solution. The molecular weights of the radicals vary from 20,000 to 40,000, and they can be precipitated by ultracentrifugation. The concentration of the asphaltenes in typical low viscosity crudes is of the order of 0·5–1 per cent. The electronic line-width in the kilomegacycle range is about 5 gauss.

The Overhauser interaction observed in the crude oil is negative; that is, the nuclear polarization at first declines with increasing intensity of the electronic radio-frequency field, becomes zero, and then builds up in opposition to the applied H_0 field. An electronic radio-frequency field (H_1) of about 0·25 gauss (at 52·6 Mc./s.) was required to drive the proton signal to zero in the specimen tested. Further increases in radio-frequency power beyond this value caused a rapid increase in the nuclear signal, in an inverted sense. The maximum available radio-frequency field, 1·1 gauss, produced an effective amplification of the proton signal of about × 15. The amplification (× 7) produced by an 0·8 gauss radio frequency field is illustrated in Fig. 1. So far as we know, the asphaltene radical is much the largest radical ever observed to produce an Overhauser polarization of solvent protons.

A rough calculation will suggest what strength of interaction is to be expected. The specimen was a highly fluid crude oil of viscosity about that of light machine oil—40 centipoise. A reasonable mean molecular weight for such an oil is 400, which leads to a molecular diameter of 10 A. If we assume the asphaltene concentration to be 0·5 per cent by weight (no accurate analysis was available for this oil), and the molecular weight to be 40,000, we find that there is one free radical for every 20,000 oil molecules. The average spacing of the radicals is therefore 270 A. From Stokes's relation, $D = kT/6\pi\eta a$, we can calculate the diffusion constant of the oil. This yields $D = 5 \times 10^{-6}$ cm.^{2}sec.$^{-1}$. A reasonable distance travelled by a typical oil molecule in the proton relaxation interval is $(DT_1)^{1/2}$. For the oil in question, T_1 was measured and found to be 186 msec. in a steady field of 18 gauss. The distance travelled by a typical proton in this time will thus be about 100,000 A. This is more than 300 times the spacing of the asphaltene radicals. The radicals occupy 3 per cent of the cross-sectional area of the solution. A typical proton, then, comes near a radical about ten times during the proton T_1 interval.

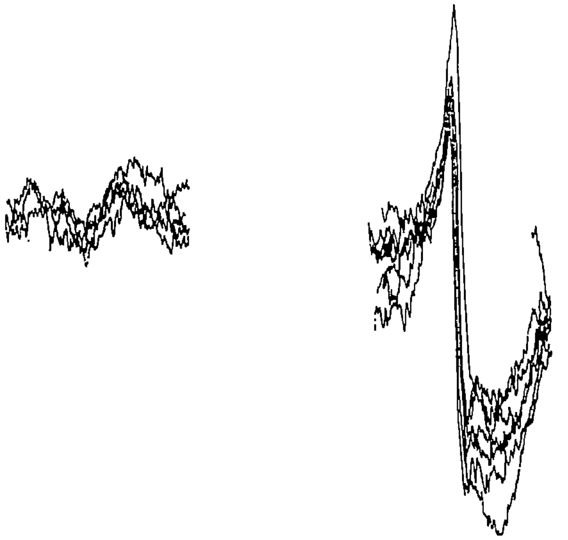

Fig. 1. Proton-resonance signals from crude oil, which demonstrate the Overhauser effect in the oil. Left, electron resonance not stimulated; right, stimulated by 0·8 gauss

At the highest available radio-frequency field the saturation parameter $S = (H_1/\Delta H)^2$ is 0·05. This would ideally lead to a proton signal amplification A of 15·5, from the relation[2] $A = 1 \cdot (S\gamma_e)$ $[2\gamma_p (1 + S)]$. The observed maximum negative amplification was about × 15. This may be rather fortuitous agreement, especially if it is considered that rather crude techniques of radio-frequency field measurement were used. It is seen, none the less, that the electron in the large asphaltene radical is essentially as effective in polarizing the adjacent fluid protons as those in much smaller radicals which have been studied to date.

Diffusion of Proteins through a Wedge-shaped Agar Gel

A WEDGE-SHAPED agar gel is formed by pouring out 10 ml. of a hot 2 per cent agar solution ('Bacto-Agar', Difco Laboratories) on a pre-warmed glass plate (16 cm. × 4 cm.), which is slightly inclined. After cooling down, the agar sets to a wedge-shaped gel. which measures 2·5 mm. at the thick end and 0·2 mm. at the thin end. It can easily be detached from the glass plate with a spatula. In the meantime another agar gel is formed, using the technique we have described for immune-electrophoresis[1]; 10 ml. of a hot 1·5 per cent agar solution are poured on a hot glass plate, as they are used in the 'Elphor' paper strip scanner. The agar gel, setting on the exactly horizontal glass plate, has a thickness of 1·5 mm. Now the wedge-shaped agar gel is laid upon it; this is done slowly so that no air remains between the two agar gels. Paper strips, 2 mm. broad, of Swedish 'Munktell' 20/150 paper are soaked in 2 per cent solutions of serum albumin (human), γ-globulin (Central Laboratory of the Swiss Red Cross, Berne) and α_2-macroglobulin (Behringwerke, Marburg/Lahn) in 0·86 per cent sodium chloride. These paper strips are laid parallel upon the wedge-shaped agar gel. After 24 hr. in a wet chamber they are removed and the agar wedge is placed on a glass plate. Both agar gels are now bathed in a 2 per cent solution of acetic acid for 2 hr. then they are dried under infra-red light and stained with amido-black.

The result shows that the thick end of the agar-wedge (Fig. 1*a*, left end) contains more of the proteins than the thin end. In Fig. 1*b* we find the proteins which have diffused through the wedge. There is slightly more serum albumin (mol. wt. 69,000, ref. 2) than γ-globulin (mol. wt. 152,000, ref. 2) and much less of the α_2-macroglobulin (mol. wt. 846,000, ref. 2).

With the same technique, but using oil red for staining, we followed the diffusion of β-lipoprotein (Behringwerke, Marburg/Lahn) and of β-lipoprotein as obtained from blood serum by dextran precipitation in the presence of calcium chloride[3,4]. The protein content of both solutions was 0·8 per cent.

The β-lipoprotein (Behringwerke, Marburg/Lahn), containing 75 per cent lipid and having an approximate molecular weight of 2,500,000, shows some diffusion (Fig. 2*b*), whereas the lipid content of the diffused precipitate is not high enough to be visibly stained by oil red. In order to increase the sensitivity we apply antiserum (horse) on the lower agar gel, after diffusion and removing the agar wedge. After 50 hr. the agar gel is thoroughly bathed in 0·86 per cent sodium chloride and non-reacting protein removed by elution. Fig. 2*c* shows what has diffused through the agar wedge. This time the paper strip was soaked in a 0·1 per cent solution of α_2-macroprotein (Behringwerke, Marburg/Lahn). The dilution compared with Fig. 1*a* is 1 : 20.

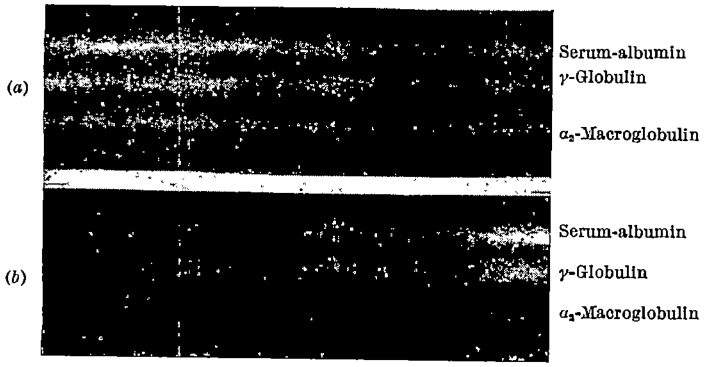

Fig. 1. (*a*). Proteins which have remained in the wedge-shaped agar-gel. (*b*) Proteins which have diffused through the above agar-gel. The thin end of the wedge is to the right

Fig. 2. (*a*) Lipoproteins which have remained in the wedge-shaped agar-gel. The thin end of the wedge is to the right. (*b*) Lipoproteins which have diffused through the above agar-gel. Oil red staining. (*c*) α_2-Macroglobulin that has diffused through the wedge-shaped agar-gel and has reacted with antiserum

The results show that the diffusion of monodispersed proteins through agar gel is slower with increasing molecular weight, but it would be difficult to give a definite value since it also depends on quantity, time and the factors which govern the structure of the gel.

Sulphydryl Groups and Ribonucleic Acid

INVESTIGATION of rat and mouse liver prepared by solvent substitution[1,2] with 1 per cent mercuric chloride in absolute methanol has shown that a considerable portion of the cytoplasmic ribonucleic acid compounds combine with mercury. The nucleic acid compounds of the nucleus do not appear to combine with mercury under the experimental conditions used, that is, cooling to −190° C. and exposing to solvent at −65° C. for 48 hr. and then warming to room temperature. It is considered likely, though not conclusively proved, that the mercury has access to the nuclei during the solvent substitution.

Absorption curves of liver nuclei in tissue substituted with mercuric chloride and methanol are identical with curves of nuclei substituted with methanol alone. The absorption curve for the cytoplasm of methanol- and mercury-substituted tissue is not identical with that for methanol-substituted, but shows a shift downwards of a portion of the nucleic acid absorption. Experiments with nucleic acid bases in solution have shown that the presence of mercury shifts the absorption maximum down to approximately 245 mμ from 265 mμ. The shift observed in the cytoplasmic curve is taken as evidence of combination with mercury.

Digestion of 10μ sections with crystalline ribonuclease (1 mgm./ml. in glass-distilled water) removed all material staining with pyronin[3] in control sections, that is, methanol-substituted, after ½ hr. In methanol- and mercury-substituted sections the nuclear material staining with pyronin was removed after ½ hr., but there was still considerable cytoplasmic staining after 1 hr. digestion. Nuclear material staining with methyl green[3] was removed by ½ hr. digestion with crystalline deoxyribonuclease from both methanol and methanol and mercury tissue.

The absorption curves, enzyme digestion and staining reactions show that the nucleic acid compounds of the nucleus do not have reactive groups available for combination with mercury under the conditions used. The same criteria indicate that a portion of the cytoplasmic ribonucleic acid is associated with groups able to combine with mercury. Combination with purine and pyrimidine bases directly or with phosphate groups seems unlikely to select a particular portion of the nucleic acid compounds. It is known that mercury salts will combine with sulphydryl groups, and it is suggested that this is occurring during the solvent substitution.

Association of nucleic acid compounds with sulphydryl groups has been suggested as involved in polypeptide synthesis[4] and the polymerization of actin[5]. The importance of sulphydryl groups during cell division has been emphasized[6], and it has recently been shown that a diffusible nucleotide[7,8] is also involved; indeed it is possible that this nucleotide is hydrogen bonded to the spindle protein through a sulphydryl group. Hydrolysis by the nucleases involves phosphate groups, and the protection of some of the ribonucleic acid compounds by mercury may involve an association of phosphate and sulphydryl groups perhaps as previously suggested[9]. The intervention of sulphydryl groups in protein synthesis is indicated by work on sulphur-starved yeast[10]. If a part at least of the role of ribonucleic acid in protein synthesis is mediated by a bond involving a sulphydryl group, then the present evidence suggests that nuclear nucleic acid compounds do not intervene in protein synthesis at the same level as the cytoplasmic compounds.

A mechanism involving sulphydryl groups offers the possibility of control by other cellular systems controlling, for example, the level of oxidation. Such a mechanism, responsive to the state of affairs in the rest of the cell, would seem to be suitable as a primary step in protein synthesis. This would place the nucleus as intervening in protein synthesis subsequent to the cytoplasmic function. It is possible that a preliminary polymerization of amino-acids in the cytoplasm is followed by a further more specific polymerization of the units by the nuclear compounds. Recent work with tracers in cells synthesizing protein has also been interpreted as demonstrating the prior role of cytoplasmic ribonucleic acid in protein synthesis[11].

An account of the investigation of mercury solvent substitution will be published elsewhere.

Mechanism of Chlorophyll Action in Photosynthesis

The use of tritiated water affords a sensitive means of answering at least one question about early photosynthetic events: Do any of the hydrogen atoms of the chlorophyll molecule intervene in the electron transport chain between water and oxidant? It has already been established[1] that all the hydrogen–carbon bonds of the chlorophyll molecule are sufficiently stable to prevent hydrogen exchange in neutral organic solvents in the dark; a tracer experiment is therefore feasible. At least one current school of thought maintains that the participation of hydrogen of the chlorophyll molecule in a chemical reaction is a requisite step in the electron transfer which originates in photoactivated chlorophyll[2]. Experiments in which *Chlorella* or *Scenedesmus* cells were illuminated in tritiated water have led us to the conclusion that some hydrogen of chlorophyll is activated during photosynthesis. A similar light-dependent and heat-sensitive activation of chlorophyll *a* and bacteriochlorophyll has been observed in a variety of cell-free preparations. The position in the chlorophyll molecule which is photochemically labilized is tentatively concluded to be C_{10}.

In the first experiments, *Chlorella* cells were suspended in tritiated water, and shaken either in the light or dark for 30 min. at 15° C., and compared with a dark control and a zero-time control. At the end of the experiment the suspensions were heated for 2 min. at 100°, the cells were lyophilized, and finally extracted with acetone. The chlorophylls were isolated by chromatography on sugar columns, and the purified material was counted in a windowless gas flow counter. Experiments 1, 2 and 3 in Table 1 show radioactivity associated with all chlorophyll samples; but chlorophyll derived from the illuminated incubation mixture has the highest specific activity. The radioactivity in the zero-time control sample was later shown to be the result of the short heat treatment, and could be reproduced with suspensions of pure chlorophyll in tritiated water. The position of tritium on the chlorophyll molecule made radioactive by heating is unknown. In subsequent experiments heating was omitted, and the algal cells were extracted without prior heating. It will be seen that in these experiments, Nos. 4 and 5, tritium is incorporated into chlorophyll only in the light. In one experiment the identity of the radioactive material with chlorophyll *a* was established by treating the biologically labelled material with 1 *N* hydrochloric acid and chromatographing the resulting phæophytin *a*. The specific activity of the phæophytin *a* was 1,155 counts per min. per mgm., and that of the original chlorophyll *a*, 1,145 counts per min. per mgm.

It will be noted that in these experiments chlorophyll *a* attained only a small fraction of the activity expected for complete equilibration of one position with the hydrogen of water. It is not known whether this reflects the participation of only a small fraction of the chlorophyll *a* in photosynthesis.

Greater differences between the tritium incorporation in the light and in the dark were observed in experiments with fragments of chloroplasts, which are known to carry out the Hill reaction. It can be seen in experiment 6, carried out with spinach leaf chloroplast fragments, that only in the light was a significant amount of tritium incorporated into the chlorophyll fraction. The absence of radioactivity from a previously heated sample indicates that the

Table 1. INCORPORATION OF TRITIUM INTO CHLOROPHYLL *a* AND BACTERIOCHLOROPHYLL

Experiment No.	Organism	C.p.m./μmole of chlorophyll				Time in min.	TOH c.p.m./μatom	Per cent equilibration
		Zero time	Boiled	Dark	Light

8	Chromatophores of *Chromatium*			0	6,500	1	40,000	16

incorporation of tritium is the result of an enzymatic reaction. Spinach leaf chloroplast fragments which have been extracted with acetone at −5° lose most of their chlorophyll, but retain a measurable part of it which is resistant to further extraction with acetone. Such acetone powder was suspended in tritiated water and exposed to light. This experiment, No. 7 in Table 1, shows that here, too, the chlorophyll becomes radioactive only in the light. This experiment is of particular significance since the specific activity of the radioactive chlorophyll indicates extensive equilibration with water. Probably only one hydrogen position participates in this reaction, and almost every molecule of chlorophyll in this reaction mixture has participated at least once. Experiment No. 8 was carried out with chromatophores of the purple sulphur bacterium *Chromatium*, prepared by Dr. I. C. Anderson of the Brookhaven National Laboratory. Like chlorophyll *a*, bacteriochlorophyll became radioactive in the light.

A number of observations suggest that the tritium on the radioactive chlorophyll *a* is located on C_{10}. Although the radioactivity remains associated with the molecule upon treatment with acid, all radioactivity passes into water when the labelled chlorophyll is treated with alkali. The label on chlorophyll *a* is quite unstable when the purified chlorophyll is exposed to air in the dry state, as for example, on nickel planchets or on paper chromatograms. This instability may be attributed to the allomerization reaction in which C_{10} is oxidized. It is thought likely that chlorophyll *a* tritiated in this position would be obtained by mild alkaline treatment of chlorophyll in tritiated water. Chlorophyll *a* was shaken in a mixture of 10 mc. of tritiated water with 0·02 ml. of pyridine in 1 ml. of ether for 12 hr. and was re-isolated by water–ether partition. The chlorophyll was found to be highly radioactive. Its radioactivity also was acid-stable, alkaline-labile, and unstable on prolonged exposure to air in the dry state. If in the previous experiments chlorophyll was indeed labelled in the C_{10} position, then chemically labelled chlorophyll *a* should be detritiated in similar reaction mixtures in the light. Table 2 shows experiments in which such detritiation by acetone powder of spinach leaf chloroplast fragments was carried out, occurred only in the light, and was heat sensitive. Attempts are in progress to purify the detritiating enzyme system and to identify possible co-factors. At this time the reaction system is in part bound to the insoluble part of the acetone powder suspension.

Table 2. LOSS OF TRITIUM FROM CHLOROPHYLL *a* LABELLED AT C_{10} DURING INCUBATION WITH ACETONE POWDER OF SPINACH LEAF CHLOROPLAST FRAGMENTS

	Residual c.p.m./μmole of chlorophyll *a*	
Zero time	148,000	
Boiled	153,000	after 30 minutes
Dark	149,000	
Light	122,000	

It is tempting to suggest that this light-dependent labelling of chlorophyll by tritium originating in water is the first step in the hydrogen transfer reaction chain in photosynthesis. There is at present one strong reason for believing that this labelling of chlorophyll is intimately related to photosynthesis. If triphosphopyridine nucleotide is added to the reaction mixture which contains a suspension of acetone powder and chemically tritiated chlorophyll *a*, there is in the light a substantial transfer of tritium from chlorophyll *a* to triphosphopyridine nucleotide. This tritium transfer must be the result of a series of reactions in which the intermediates do not exchange hydrogen with water, since any amount of exchange would have diluted the tritium below detection-levels. The details of these and related experiments will be presented elsewhere.

Bacterial Preparation of Orotidine-5′-phosphate and Uridine-5′-phosphate

THE enzymic syntheses of orotidine-5′-phosphate and uridine-5′-phosphate have been reported by Lieberman *et al.*[1] and others. A chemical phosphorylation of uridine to form the 5′-phosphates has also been described by Hall and Khorana[2]. This communication describes the preparation of these previously rare compounds from cultures of *E. coli B* grown in a salts–glucose medium in the presence of the uracil analogue, *as*-triazine-3,5-dione, referred to as 6-azauracil.

It was reported previously that 6-azauracil inhibits the growth of various micro-organisms[3,4] and that nucleoside and nucleotide metabolities of the analogue could be isolated from the culture medium[5] or from the inhibited cells[6]. Using a modification of the method described by Skoda *et al.*[5] for the ribosidation of 6-azauracil by *E. coli B* to form 6-azauracil riboside (azauridine), large amounts of normal pyrimidine metabolities also were found in the medium. These have now been characterized as orotic acid, orotidine- and uridine-5′-phosphates. In a typical preparative run, 20 l. of a salts–glucose synthetic medium[8] containing 0·5 mmole/l. of 6-azauracil were inoculated with 2 l. of an uninhibited 18-hr. culture of *E. coli B* and incubated at 25° for 24 hr. without aeration. Growth, as judged by turbidity, was approximately one-third that of an uninhibited culture. The entire culture, without removal of the cells, was passed through a 100-gm. column of 'Darco' 20–40 granular charcoal, and the adsorbed pyrimidine derivatives were eluted with 50 per cent ethanol containing 2 per cent concentrated ammonium hydroxide. Following concentration *in vacuo* to a small volume, a crystalline precipitate was removed by filtration and characterized as ammonium orotate (700 mgm.). The filtrate was diluted, adjusted to *p*H 8·5, and passed through a 2 cm. × 20 cm. column of 'Dowex' 1 × 4 (formate) (200–400 mesh) anion resin. Elution with 0·1 *N* formic acid removed azauridine (1,140 mgm.) and a small amount of unconverted 6-azauracil. The solution of azauridine was concentrated to dryness, and the residue was recrystallized from water and ethanol. The column was then subjected to gradient elution with water and 1 *N* ammonium formate (*p*H 3·8) until two major ultra-violet-absorbing materials were removed. That the first of these was uridine-5′-phosphate (35 mgm.) was indicated by the ultra-violet-absorption characteristics and by ribose content, periodate titration, phosphate analysis, paper chromatography in four systems and perchloric acid digestion to release free uracil. The second substance was characterized in the same manner as the first; the analytic results indicated that it consisted of orotidine-5′-phosphate (73 mgm.). Both nucleotides were further purified by rechromatography on 'Dowex' 1 ion-exchange columns. The yields of uridine-5′-phosphate are variable, and in small-scale cultures occasionally none is found; yields of orotidine-5′-phosphate are generally greater when those of uridine-5′-phosphate are low. The reasons for this and further data on the mechanism of this accumulation are to be reported in detail elsewhere. From the charcoal eluates of a 625-gallon culture of *E. coli* inhibited by 6-azauracil, kindly supplied by the Squibb Institute for Medical Research, 65 gm. of orotic acid, 13 gm. of uridine-5′-phosphate and 6 gm. of orotidine-5′-phosphate have been isolated. Small amounts of phosphorylated derivatives of azauridine also were present in the charcoal eluate from the small-scale preparations and were recovered during ion-exchange chromatography. These correspond to those substances, previously referred to, which occur in the acid-soluble extract from *S. faecalis* cells[6] inhibited with 6-azauracil.

Apart from the preparative potential of this simple system for pyrimidine nucleotides, the significance of the accumulation of orotic acid and orotidine-5′-phosphate, with respect to the mode of action of the antimetabolite 6-azauracil, is apparent. A blockage in the utilization of pyrimidine derivatives at the ribotide level is suggested; in fact, enzymatic studies reported elsewhere[7] have attributed the interference to an inhibition of orotidylic decarboxylase.

It is of interest from a biosynthetic point of view that approximately 1 gm. of ribose in nucleoside or nucleotide linkage and 1·0 gm. of pyrimidine derivatives are produced in a salts–glucose medium from an inhibited culture which contained approximately 1 gm. (dry weight) of bacterial cells. In the absence of 6-azauracil there is little or no accumulation of these pyrimidine derivatives in the culture medium and the additional approximately 2 gm. (dry weight) of bacterial cells which would have been formed could not have contained more than 200 mgm. of pyrimidine-derivatives. It may be inferred that 6-azauracil acts not only to prevent further utilization of these nucleotides but also to suppress a mechanism which, under normal conditions of growth, limits their formation.

I wish to thank workers in the Squibb Institute for Medical Research, New Brunswick, New Jersey, for their generous help in the processing of large cultures. The present work was supported by a scholar appointment from the American Cancer Society and funds from the U.S. Public Health Service Grant *C*-2817.

Mode of Action of 5 : 6-Dimethylbenzimidazole and Certain Keto-Acids as Inhibitors of Hæm Biosynthesis

Abbott and Dodson[1] reported an inhibition by 5 : 6-dimethylbenzimidazole of the incorporation of ^{15}N-glycine into hæm by chicken erythrocyte preparations. Later work by Abbott, Dodson and Auvil[2] showed that this inhibition is at a step prior to the formation of δ-aminolævulic acid in the biosynthetic pathway. Recently, it has been reported[3] that the inhibition is to be located in those steps of δ-aminolævulic acid synthesis which involve either activation of glycine, in which pyridoxal phosphate is concerned, or condensation of the activated glycine derivative with succinyl-coenzyme *A*. Production of succinyl-coenzyme *A* itself is not inhibited by 5 : 6-dimethylbenzimidazole in the chicken erythrocyte preparations used[3]. Evidence has been presented recently[4] for the involvement of ferrous iron in the biosynthesis of δ-aminolævulic acid; work described at the same time showed that ferrous iron consistently diminished the inhibition by 5 : 6-dimethylbenzimidazole of δ-aminolævulic acid biosynthesis. Several other metal ions examined, including ferric iron, did not have this effect.

Present work has shown that riboflavin, a good chelating agent for ferrous iron[5], also inhibits the biosynthesis of δ-aminolævulic acid and that the inhibitions obtained with riboflavin, 5 : 6-dimethylbenzimidazole and α-α′-dipyridyl[4] are not additive (Table 1), so suggesting a similar mode of action as inhibitors, that is, the binding of ferrous iron.

If this hypothesis were correct it might be expected that 5 : 6-dimethylbenzimidazole would also inhibit the last stage of hæm synthesis, which involves the incorporation of ferrous iron into the porphyrin ring system. This was tested using lysed chicken erythrocyte preparations and assaying the incorporation of iron-59 into hæm. The method used was that described by Goldberg, Ashenbrucker, Cartwright and Wintrobe[6]. Table 2 shows the results so obtained, and Table 3 the results obtained from a parallel series of incubations in which porphyrin production was estimated by the method of Dresel and Falk[7]. Comparison of Tables 2 and 3 indicates an inhibition of hæm synthesis at two levels: (1) prior to δ-aminolævulic acid formation; (2) between protoporphyrin and hæm production. This finding confirms the hypothesis that 5 : 6-dimethylbenzimidazole inhibits steps requiring ferrous iron, the most likely mechanism being binding of the metal by co-ordination at the nitrogen atom (N_1) of the imidazole ring. It has been observed, in this connexion, that N_1-substituted benzimidazoles are without inhibitory effect.

Inhibition of hæm synthesis in bone marrow homogenates by α-oxoglutarate has been reported by Richmond, Altman and Salomon[9]. This inhibition has been demonstrated, in chicken erythrocyte preparations, to be located at those steps of δ-aminolævulic acid synthesis where 5 : 6-dimethylbenzimidazole mediates its effect[3]. Again, using extracts of *Rhodopseudomonas spheroides* which synthesize δ-aminolævulic acid, Shemin, Kikuchi and Bachmann[10] have shown an inhibition by both α-oxoglutarate and pyruvate. It has been suggested that inhibition by keto-acids might be attributable to a shunting of pyridoxal-5′-phosphate from δ-aminolævulic acid synthesis to transamination processes involving the added keto-acids[9]. Another school has suggested that pyruvate might compete with succinyl-coenzyme *A* for 'activated glycine'[11].

In view of the observation, already mentioned, that α-oxoglutarate appears to exert its inhibitory effect at a similar stage, in the biosynthesis of δ-aminolævulic acid, to 5 : 6-dimethylbenzimidazole, and taking into consideration the evidence obtained for the action of 5 : 6-dimethylbenzimidazole as a binding agent for ferrous iron, it seemed feasible that α-oxoglutarate and pyruvate might be acting in the same way. In this case, however, binding of metal ions would be expected to take place by chelation by the enol form of the respective keto-acids. Following this idea, experiments were conducted to examine the effect of ferrous iron on the inhibitions produced by α-oxoglutarate and pyruvate in chicken erythrocyte preparations which synthesize δ-aminolævulic acid without concomitant production of porphobilinogen or porphyrins[3]. The results, recorded in Table 4, show that ferrous sulphate produces marked alleviation of the inhibitions obtained with both α-oxoglutarate and pyruvate, so offering some support for the above hypothesis.

Table 1. NON-ADDITIVE INHIBITIONS OF δ-AMINOLÆVULIC ACID BIOSYNTHESIS WITH 5 : 6-DIMETHYLBENZIMIDAZOLE AND RIBOFLAVIN OR α-α′-DIPYRIDYL

Additions	δ-Aminolævulic acid (μmole)	Inhibition (per cent)
Exp. 1		
None	210	—
5 : 6-Dimethylbenzimidazole (2·7 m*M*)	44	79
Riboflavin (0·5 m*M*)	66	69
5 : 6-Dimethylbenzimidazole + riboflavin (0·5 m*M*)	43	80
Exp. 2		
None	220	—
5 : 6-Dimethylbenzimidazole (2·7 m*M*)	79	64
α-α′-Dipyridyl (1 m*M*)	172	22
5 : 6-Dimethylbenzimidazole (2·7 m*M*) + α-α′-dipyridyl (1 m*M*)	73	67

Incubations conducted under standard conditions (ref. 3) with 30 m*M* glycine and 30 m*M* citrate. Chicken erythrocyte preparation (ref. 3).

Table 2. EFFECT OF 5 : 6-DIMETHYLBENZIMIDAZOLE ON HÆM SYNTHESIS

Additions	Hæmin isolated (mgm.)	Activity of hæmin (^{59}Fe) counts/min./mgm.
Glycine (30 m*M*) + succinate (30 m*M*)	25·9	27
Glycine (30 m*M*) + succinate (30 m*M*) + 5 : 6-dimethylbenzimidazole (6·8 m*M*)	19·1	8
δ-Aminolævulic acid (0·4 m*M*)	12·8	22
δ-Aminolævulic acid (0·4 m*M*) + 5 : 6-dimethylbenzimidazole (6·8 m*M*)	21·6	9

Chicken erythrocyte lysate prepared and incubated as described by Goldberg *et al.* (ref. 6). ^{59}Fe-hæmin was isolated and counted as described by these authors.

Table 3. EFFECT OF 5 : 6-DIMETHYLBENZIMIDAZOLE ON PORPHYRIN SYNTHESIS

Additions	Uroporphyrin (μgm.)	Coproporphyrin (μgm.)	Protoporphyrin (μgm.)
Glycine (30 m*M*) + succinate (30 m*M*)	—	—	22
Glycine (30 m*M*) + succinate (30 m*M*) + 5 : 6-dimethylbenzimidazole (6·8 m*M*)	—	—	7
δ-Aminolævulic acid (0·4 m*M*)	131	75	401
δ-Aminolævulic acid (0·4 m*M*) + 5 : 6-dimethylbenzimidazole (6·8 m*M*)	137	80	420

Chicken erythrocyte lysate prepared and incubated as described by Dresel and Falk (ref. 8). Porphyrin separations and estimations were made following the procedure of these authors (ref. 7).

Table 4. EFFECT OF FERROUS SULPHATE ON THE INHIBITION OF δ-AMINOLÆVULIC ACID SYNTHESIS BY KETO-ACIDS

Additions	δ-Aminolævulic acid (μmmole)
None	154
$FeSO_4$ (1 m*M*)	118
α-Oxoglutarate (10 m*M*)	76
α-Oxoglutarate (10 m*M*) + $FeSO_4$ (1 m*M*)	106
Pyruvate (10 m*M*)	27
Pyruvate (10 m*M*) + $FeSO_4$ (1 m*M*)	65

Incubation conducted under standard conditions (ref. 3) with 30 m*M* glycine and 30 m*M* citrate. Chicken erythrocyte preparation (ref. 3).

This work, which was carried out during the tenure of an I.C.I. Research Fellowship, will be reported in full elsewhere. I wish to thank Prof. C. Rimington for his interest and advice and Miss B. Knight for technical assistance.

Colour Vision Studies and the X-Chromosome Constitution of Patients with Klinefelter's Syndrome

WE wish to report confirmation of the presence of two *X*-chromosomes in males with Klinefelter's syndrome and female nuclear sex and their presumptive 'sex-reversal'.

In 1949 Barr and Bertram[1] described a sexual dimorphism in intermitotic nuclei and suggested that the presence of 'sex-chromatin' (female nuclear sex) was dependent on the presence of two *X*-chromosomes. It has been assumed that the absence of 'sex-chromatin' (male nuclear sex) as in normal males, could be taken to imply an *XY* sex-chromosome combination. The validity of this identity is supported by many facts but does not amount to absolute proof. Caution is required in drawing conclusions from nuclear sexing about the *X*-chromosome constitution in anomalies of sexual differentiation, particularly those with apparent sex-reversal, because chromosomal anomalies are possible in these conditions and may lead to faulty inferences from the nuclear sex findings. Therefore the results of nuclear sexing in such cases should be confirmed by non-cytological genetic means[2]. The results of colour-vision studies can be used as tests of the *X*-chromosome constitution in groups of individuals with anomalies of sexual differentiation resulting in a discrepancy between somatic appearances and nuclear sex. Major red–green colour vision defects are determined by recessive genes located in the non-homologous portion of the *X*-chromosomes and therefore are much more common among males than among females, who must be homozygous for the genes in order to manifest the trait.

Colour vision tests on a group of subjects of female phenotype with evidence of 'ovarian agenesis' (gonadal dysgenesis) and with male nuclear sex, suggesting a male sex-chromosome constitution, showed that nuclear sexing had accurately depicted the absence of the *XX* chromosome combination and thus proved that they were not females in the sense of their sex-chromosome constitution[2]. It was not possible to obtain non-cytological genetic evidence on the *Y* sex-chromosome because of the absence of demonstrable complete *Y*-linked genes, though now that the work of Ford and his colleagues[3] has made direct detection of this chromosome possible the answer should be forthcoming. In Klinefelter's syndrome, a condition of sterility in males with abnormally small testes[4], a proportion of patients have a female nuclear sex pattern and the inference is that they have an *XX* sex-chromosome constitution. It was suggested[5] that their colour vision should be studied to confirm this and a preliminary assessment[6] showed a trend in this direction. The study has since been extended and the results to date are given in Table 1.

The incidence of major colour vision defects in the population of England, as tested on the Ishihara Tables, is 7–8 per cent for males and 0·65 per cent for females[7]. The figures for Switzerland are about 8 per cent for males and 0·43 per cent for females[8].

Table 1. Ishihara Colour Vision Tests in Patients with Klinefelter's Syndrome

	Total tested	Colour vision normal	Major colour vision defect: Observed	Expected if sample were of males*	Expected if sample were of females†
Patients with female nuclear sex (presumptive *XX*)	55‡	55	0	4·40	0·36
Patients with male nuclear sex (presumptive *XY*)	38‡	34	4	3·04	0·25

* Based on an 8 per cent incidence of major colour vision defects among males.

† Based on a 0·65 per cent incidence of major colour vision defects among females.

‡ 47 patients from Glasgow, 35 from London and 11 from Zurich.

The findings on colour vision in the sample of 55 chromatin-positive patients with Klinefelter's syndrome are significantly different from those that should be found in a sample of males, and therefore our results confirm the inference of nuclear sexing, that these patients, though phenotypic males, have in fact two *X* sex-chromosomes.

Recently, Ford and his colleagues[3] have found chromosome combinations of female type in a culture of bone marrow cells from one patient with Klinefelter's syndrome, thus giving the first direct cytological confirmation to the nuclear sexing result in the case submitted to them for study.

We are grateful to Dr. D. Ferriman for information about four of his patients included in the London series and to all the other colleagues who referred their cases to us.

Lowering of an Auditory Threshold produced by a Light Signal occurring after the Threshold Stimulus

It has previously been shown that the interval between a warning signal and a subsequent stimulus will affect the threshold-level for perception of the stimulus[1,2]. When the interval between the warning signal and the threshold stimulus was kept constant, and was known to the subject beforehand, the threshold was lowest for a 1-sec. interval and was progressively higher for intervals of 2, 3, 4 and 9 sec. When the warning intervals were used in random order so that the subject did not know when, within the range, to expect the stimulus, the effect did not appear. This rules out an explanation in terms of intersensory facilitation.

This experiment has now been extended to warning intervals of 0, 0·3, 0·6, 0·9 and 1·5 sec. in one experiment and 0·05, 0·1, 0·15, 0·2 and 0·3 sec. in another, with the result that the threshold was lowest for the shortest interval in both cases. By analogy with reaction time and conditioning experiments, one might have expected the greatest 'readiness' and thus the lowest threshold to occur some time after the warning signal.

The following experiments confirm these results, and also extend the observations to the use of a 'warning' signal after the threshold stimulus.

The threshold stimulus was an increase, lasting about 50 msec., in the intensity of a 500-c.p.s. tone 60–70 decibels above threshold. The warning signal was a neon bulb lighting up. Another neon served as a 'get ready' signal before each trial, and the interval between it and the warning neon varied randomly between 2 and 7 sec., to prevent it acting as an effective warning. In each series of twenty trials, the interval between the 'warning' neon and the threshold stimulus was constant, and known to the subject. Four each of four intensities, and four zero or blank stimuli, occurred in each series in random order. The thresholds were calculated by probit analysis.

In the first experiment, intervals of −0·5 sec. (that is, the neon came on half a second after the threshold stimulus) and −0·1 sec. were compared with 'no warning' series, in which the second neon did not light up. In the second experiment, intervals of −0·1, 0 and +0·1 sec. were used. The simultaneous condition gave the lowest threshold, and even when the second neon came on 0·5 or 0·1 sec. after the threshold stimulus, it significantly lowered the threshold, as is shown in Table 1.

Table 1

	Experiment 1			Experiment 2		
Warning interval	'No warning'	−0·5	−0·1	−0·1	0	+0·1
Threshold (db.)	0·34	0·31	0·30	0·27	0·23	0·28
Standard errors	0·007	0·007	0·006	0·006	0·007	0·006
False positive rate (per cent)	10·0	6·3	8·1	8·8	7·5	11·9

These results might have been due to the subjects trying harder on some series. To exclude this possibility, a third experiment was done, in which trials under the −0·5 condition and the 'no warning' condition occurred in random order. The thresholds were 0·30 ± 0·013 decibel and 0·37 ± 0·010 decibel, and the false alarm rates 4·0 and 4·5 per cent, respectively, showing that the effect is still there even when 'set' is excluded.

These results imply that in experiments involving accurate threshold determinations not only should all possible preceding warnings be controlled but also any cues occurring up to at least 0·5 sec. after the stimulus. They also provide evidence that the effects of stimuli, unable by themselves to determine a perception or response, may be stored for brief periods.

That the threshold in these experiments is not lowered by intersensory facilitation is shown by the negative result in our earlier experiment with randomized warning intervals, and by the still large effect when the 'warning' occurs 0·5 sec. after the threshold stimulus. Experiments by Barlow[3] and by Tanner and Swets[4] have shown that the deliberate lowering of a visual threshold, by instructions or by motivation, results in an increased false alarm rate, and Barlow also found a decrease in the slope of the frequency of response curve when measured on a logarithmic scale. Both are unaffected by the changes in threshold in our experiments, suggesting that the lowering of the threshold is accompanied by, and may be the result of, a decrease in the effective 'noise' in the system. Such a decrease in 'noise' could be due to the 'warning' signal reducing the subjects' uncertainty about just when the threshold stimulus will occur. This uncertainty would be at a minimum when the 'warning' and the threshold stimulus are simultaneous.

New Plant Growth-Substances with Selective Herbicidal Activity

The pronounced effect on plant growth-regulating activity that results from the introduction of chlorine atoms into certain positions of the benzene ring in benzoic and phenoxyacetic acids is well known[1], and some of these active derivatives, for example, 2 : 4-dichlorophenoxyacetic acid (2 : 4D), 2 : 4 : 5-trichlorophenoxyacetic acid (2 : 4 : 5T) and 2 : 3 : 6-trichlorobenzoic acid have become widely used for selective weed control. Systematic investigations with these groups of compounds have provided much information on the structural requirements necessary for high growth-regulating activity[2]. The influence of nuclear substitution on the activity of phenylacetic acids, however, has not received much attention, although some of these compounds have been examined (see Pybus[3]).

All the mono- and di-chlorophenylacetic acids, together with certain analogous trichloro-derivatives, have recently been prepared in this laboratory and their growth-regulating activity has been assessed in the wheat cylinder, pea segment and pea curvature tests[3]. During this investigation, the activity in the above three tests of all the corresponding benzoic and phenoxyacetic acids was re-examined for comparative purposes. With phenoxyacetic acids, high activity occurs only when a substituent group such as chlorine is present in the *para*-position of the ring; thus, for example, the 4-chloro-, 2 : 4- and 3 : 4-dichloro-, 2 : 3 : 4- and 2 : 4 : 5-trichloro-acids are all highly active[4]. In the benzoic series, however, compounds substituted in the *para*-position possess only weak activity; when this position is free, high activity is found to be associated with *ortho*-substitution. Thus the 2 : 3-, 2 : 5- and 2 : 6-dichloro- and 2 : 3 : 6-trichloro-benzoic acids are all active compounds[5].

With the phenylacetic acids, we have found that all the mono- and di-chloro-derivatives exhibit activity[3], the 2 : 3- and 2 : 6-compounds being extremely active. The high activity of 2 : 3- and 2 : 6-dichlorophenylacetic acids led logically to an examination of 2 : 3 : 6-trichlorophenylacetic acid and, as expected, this compound proved extremely active. The performance of these three acids in our standard laboratory tests, together with those of the corresponding benzoic and phenoxyacetic derivatives, are presented in Table 1, where comparable data for the activity of 2 : 4-dichlorophenoxyacetic acid are also given. The results clearly reveal the high growth-promoting properties of 2 : 3- and 2 : 6-dichloro- and 2 : 3 : 6-trichlorophenylacetic acids. It will be noted that the activity of the 2 : 3- and 2 : 3 : 6-derivatives in these tests was at least equal to that of 2 : 4D and far superior to that shown by the corresponding 2 : 3-dichloro- and 2 : 3 : 6-trichlorobenzoic and phenoxyacetic acids.

Table 1. GROWTH-PROMOTING ACTIVITY IN THE WHEAT CYLINDER, PEA SEGMENT AND PEA CURVATURE TESTS* OF 2 : 3- AND 2 : 6-DICHLORO- AND 2 : 3 : 6-TRICHLORO-DERIVATIVES OF BENZOIC, PHENYLACETIC AND PHENOXYACETIC ACIDS†. THE ACTIVITY OF 2 : 4-DICHLOROPHENOXYACETIC ACID IN THESE TESTS IS ALSO GIVEN

Acid	Concentrations tested (molar)														
	Wheat cylinder test :					Pea segment test :					Pea curvature test :				
	×10^{-7}	×10^{-6}	×10^{-5}	×10^{-4}	×10^{-3}	×10^{-7}	×10^{-6}	×10^{-5}	×10^{-4}	×10^{-3}	×10^{-7}	×10^{-6}	×10^{-5}	×10^{-4}	×10^{-3}
2 : 3-Dichlorobenzoic	101	102	109	*125*	*121*	100	102	105	*117*	*120*	0	0	1	2	3

* The responses obtained in all tests were assessed after a 24-hr. treatment period. In the wheat cylinder and pea segment tests, activity is expressed as a percentage of the final length of control segments. Figures in italics are significantly different from controls at the 0·1 per cent level. In the pea curvature test, activity was assessed using a scale from 0 (inactive) to 6 (highly active).

† All compounds were examined at the stated concentration of the acid in the form of its sodium salt.

The marked activity of these three phenylacetic acids in our laboratory tests prompted us to investigate their effect on weed and crop plants. The results of experiments carried out to date indicate that all show selective herbicidal activity, and that the 2 : 3- and 2 : 3 : 6-derivatives are as effective as 2 : 4D in controlling many weed species. Further investigations on the herbicidal properties of these compounds and their effect on crop plants would appear to be warranted.

Relationship between the Presence of Fungal Spores and a Test for Hepatotoxic Grass

FOLLOWING warm autumn rains after summers of above-average temperatures, rapidly growing pastures in some districts of New Zealand are capable of producing an hepatotoxin causing serious losses in sheep and cattle. A minority of the affected animals exhibit the clinical symptoms described as 'facial eczema'[1].

When heat-dried pasture samples containing the toxin are fed for 35 days, guinea pigs show liver damage. Using this tedious bio-assay technique, White[2] has been able to prepare extracts containing the toxin, but progress has been delayed through the lack of a specific chemical test. Recently, White[3] isolated a substance containing a major component of m.p. 260° C., and this has formed the basis of the so-called 'beaker test', a 4 hr. routine acetone extract procedure[4]. The occurrence of this substance in pasture samples, highest yield being 1 in 50,000 of dry weight of pasture, has been correlated with toxicity by Perrin and Sandos[5] and Clare and Sandos[6]. In spite of a good correlation, there is no evidence for chemical alliance between the 'beaker test' substance and the toxin. The purpose of this communication is to record the presence of fungal spores on pasture samples giving positive 'beaker tests'.

The original 'beaker test'–toxicity relationship was established from pasture samples obtained from the Claudelands Show Ground, Hamilton. Recently, on March 13, 1958, a positive 'beaker test' was obtained from pasture cut from this same area, and on March 15 fungal mycelia were observed on and about dead leaves and leaf bases of grasses. Direct isolation of hyphæ for growth on culture media showed that a species of *Sporidesmium*, identified by the Commonwealth Mycological Institute, Kew, as *S. bakeri* Syd. (Herb. I.M.I. No. 74473), was present in all samples examined. Other fungi isolated included a species of *Fusarium* and members of the Mucorales. On March 24, dark brown spore masses, consisting mainly of *Sporidesmium* spores, were observed on a gang-mower used to cut the Claudelands area. This material gave a positive 'beaker test'. Other samples of less pure spore material scraped from the mower were also found to give positive 'beaker tests', with the major component of m.p. 260° C. present at a level of 1 : 5,000.

Various strains of *S. bakeri* obtained from samples of mycelia on grass collected on March 15 were then grown on various media and a high sporing strain on particular media gave positive 'beaker tests'. Pasture samples collected daily between March 13 and 19 which had been dried were afterwards fed to guinea pigs. These tests showed that the toxin was present in the grass on March 15 and in the samples cut on each of the other days of this period.

Past work in which samples of toxic pasture have been dissected into dead and green portions has shown that stronger 'beaker tests' have been obtained from the dead material but that the toxin was present mainly in the green material. Positive 'beaker tests' have sometimes been obtained at intervals ranging from 0 to 14 days, before toxicity appeared, and pastures have produced positive 'beaker tests' for several weeks after the disappearance of the toxin. From this it will be clear that not all samples giving a positive 'beaker test' contain the toxin. However, it is only rarely that the toxin is found in samples not giving a positive 'beaker test'.

Recently a pure perennial ryegrass pasture at Palmerston North has caused facial eczema in sheep. Samples of these pastures supplied by Butler[7] have proved positive to the 'beaker test', and it is of considerable interest that direct microscopical examination of the surface of these leaves confirmed the presence of many *Sporidesmium* spores. A culture of *S. bakeri* has since been obtained from this material by direct hyphæ isolation.

These observations indicate that the substance giving the 'beaker test' reaction is contained in the spores of *S. bakeri*. E. P. White (personal communication) has confirmed this by isolation of the material with m.p. 260° C. in an impure state from cultured spores. An investigation is being carried out to determine whether this fungus also produces the toxin.

Composition of the Nucleic Acids of Some Algae

As part of a study on the chemical composition of algae[1], the composition of the nucleic acids of various algae was investigated in order to determine whether there were differences between different groups of marine and freshwater forms. The following algae were studied: the freshwater diatoms *Navicula pelliculosa* (Bréb.) Hilse and *Nitzschia palea* (Kütz.) W. Sm.; the marine diatom *Cylindrotheca gracilis* (Bréb.) Grun.; the freshwater blue-green alga *Anacystis nidulans* (Richt.) Dr. and Daily; and the freshwater green alga *Chlorella pyrenoidosa* Chick.

The algae were grown in sterile culture. The flasks, containing 1·5 l. of suitable medium, were kept in a temperature-controlled room and illuminated from below with daylight fluorescent light. The algae were harvested every ten days to two weeks by centrifugation. *Navicula pelliculosa* and *Nitzschia palea* were grown at 22° C. in modified Chu 14 medium[2], illuminated intermittently and aerated. *Cylindrotheca gracilis* was grown in sea-water with a salinity of 17,000 p.p.m. with the addition of Ketchum and Redfield's medium[3]; a mixture of air and 2–5 per cent carbon dioxide was bubbled through the flasks. *Chlorella pyrenoidosa* was grown in modified Bristol's solution[4], illuminated continually and aerated with the air–carbon dioxide mixture. *Anacystis nidulans* was grown at 36° C. in Kratz and Meyers's medium[5], continually illuminated and aerated with the air–carbon dioxide mixture.

For the isolation of the nucleic acids and their separation into ribonucleic acid and deoxyribonucleic acid, the method of Ogur and Rosen[6] was used. Ultra-violet absorption spectra of all fractions were determined, and paper partition chromatograms were prepared. The most successful solvents were acidic butyl and propyl alcohol mixtures (*n*-butyl alcohol 77 : formic acid 10 : distilled water 13; or *iso*-propyl alcohol 68 : concentrated hydrochloric acid 17·5 : distilled water 14·5). Ribonucleic acid and deoxyribonucleic acid were hydrolysed with 3 *N* perchloric acid for 1½ hr. at 100° C. After determining their ultra-violet absorption curves, the hydrolysed samples were cooled in an ice-bath, neutralized with an ice-cold saturated solution of potassium hydroxide, filtered to eliminate the potassium perchlorate, concentrated *in vacuo*, and chromatographed. The purines and pyrimidines were eluted with 0·1 *N* hydrochloric acid according to Wyatt[7], and their amounts determined spectrophotometrically.

Repeated isolations and determinations of the ultra-violet absorption spectra of ribonucleic acid and deoxyribonucleic acid from all the organisms mentioned above showed no significant variations from the typical preparations of these acids from other sources. Samples of ribonucleic acid from all organisms showed the presence of the following purines and pyrimidines: cytosine, uracil, adenine and guanine. Cytosine, thymine, adenine and guanine were found in deoxyribonucleic acid. 5-Methylcytosine could not be detected in any of the algae studied. The quantitative data on the deoxyribonucleic acid from the algae were determined on the basis of millilitres of packed cells used. Although this is not an entirely accurate and reproducible unit, it is adequate for the determinations of the ratios of adenine/thymine, guanine/cytosine and purine/pyrimidine as previously determined by Wyatt for insect viruses[8]. The ratios varied from 1·01 to 1·10 for adenine/thymine, from 0·99 to 1·06 for guanine/cytosine, and from 1·01 to 1·09 for purine/pyrimidine (Table 1).

Table 1

Organism	Molar ratios in deoxyribonucleic acid		
	$\frac{\text{Adenine}}{\text{Thymine}}$	$\frac{\text{Guanine}}{\text{Cytosine}}$	$\frac{\text{Purine}}{\text{Pyrimidine}}$
Navicula pelliculosa	1·01	1·06	1·03
Nitzschia palea	1·09	0·99	1·04
Cylindrotheca gracilis	1·02	1·00	1·01
Anacystis nidulans	1·04	1·08	1·04
Chlorella pyrenoidosa	1·10	1·08	1·09

Effect of Giberellic Acid on Leaf Form

RECENT reports[1,2] show that gibberellic acid affects the production of the juvenile or adult leaf form in plants. In the course of a study of the effect of physiologically active substances on heteroblastic development in *Ipomoea caerulea*, plants have been treated with various substances, including gibberellic acid. The observations so far made may be of interest in considering the effect of this substance on leaf form in other plants.

The substances used have been applied as drops (0·01 ml.) of aqueous solution on the cotyledons of 4–5 day-old seedlings. Indole-3-acetic acid, 2-4-dichlorophenoxyacetic acid, α-naphthylacetic acid, 2,3,5-triiodobenzoic acid and gibberellic acid have been applied in this way. The amount of substance applied was usually 10 μgm., except in the case of 2,4-dichlorophenoxyacetic acid, which was toxic in amounts greater than 5 μgm., and indole-3-acetic acid, which showed no appreciable effects unless applied in amounts of up to 50 μgm. As can be seen from Fig. 1 all these substances caused a delay in the change from the juvenile stage in which the leaves are entire (leaf shape index 1) or of low shape index (measured as described in previous work[3]), to the adult stage in which the leaves are tri-lobed and have a high shape index. 2,3,5-Triiodobenzoic and gibberellic acids, especially the latter, have particularly marked effects. This effect of gibberellic acid in maintaining the juvenile stage is similar to its effect on *Hedera* reported by Robbins[1], but in *Hedera* it is the juvenile leaf that is lobed while the adult form is entire, the reverse being the case in *Ipomoea*. In *Eucalyptus*, on the other hand, gibberellic acid produces the leaf-form characteristic of the adult plant[2]. The mechanism by which gibberellic acid produces these varying effects on leaf form is not yet clear. Brian[4] has suggested a possible mechanism of gibberellic acid action on flowering and germination.

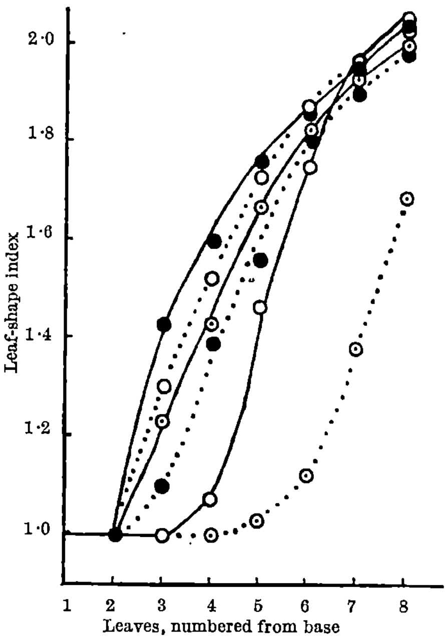

Fig. 1. The effect of various substances on leaf shape in *Ipomoea caerulea*. ●——●, control; ○ . . . ○, indole-3-acetic acid, 50 μgm.; ⊙——○, α-naphthylacetic acid, 10 μgm.; ● . . . ●, dichlorophenoxyacetic acid, 0·5 μgm.; ○——○, 2,3,5-triiodobenzoic acid, 10 μgm.; ⊙ . . . ⊙, gibberellic acid, 10 μgm.

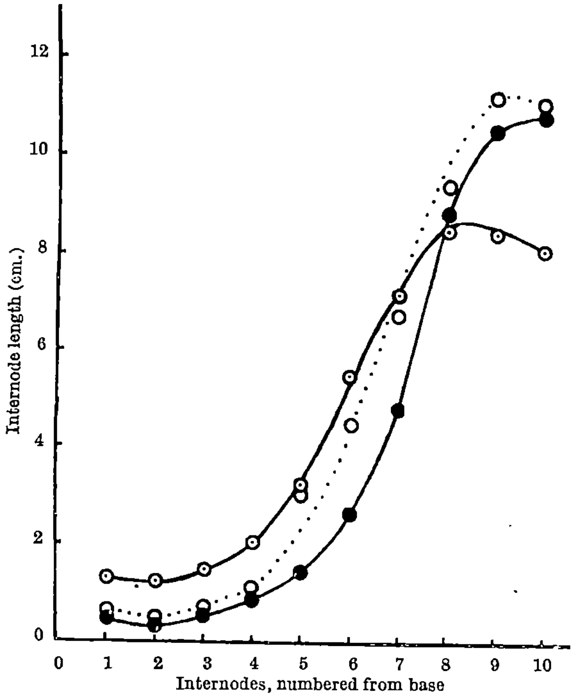

Fig. 2. The effect of 2,3,5-triiodobenzoic and gibberellic acids on internode-length in *Ipomoea caerulea*. ●——●, control; ○ . . . ○, 2,3,5-triiodobenzoic acid, 10 μgm.; ⊙——⊙, gibberellic acid, 10 μgm.

Further experiments with 2,3,5-triiodobenzoic and gibberellic acids have shown that, associated with their effects on leaf-form, are other changes in the growth pattern of treated plants. Both substances have a pronounced effect on internode-length, which is considerably increased (Fig. 2). The effect of gibberellic acid is, however, reversed at the higher internodes so that the height of the treated plants after four weeks growth is about the same as that of the control plants. This compensatory effect is similar to that observed by other workers and discussed by Humphries[5]. Dry-weight determinations made a week after treatment show that there are also changes in the distribution of growth between various organs (Table 1). Both substances have a stimulatory effect on shoot growth as shown by increased leaf production and increased stem and leaf weights. There is little or no effect on root growth, with the result that the root weight is a smaller percentage of total weight in treated plants. More work is required to show whether the change in root ratio is of fundamental importance in explaining the effect on leaf form. It is known that under conditions of shade when the juvenile leaf form is maintained the root ratio is low. Greater shoot growth and increased leaf production are also

Table 1. THE EFFECT OF GIBBERELLIC ACID ON GROWTH IN *Ipomoea caerulea*

Treatment	Leaf weight mgm./plant	Stem weight mgm./plant	Root weight mgm./plant	Total weight mgm./plant	Root weight as per cent of total	No. of leaves
Control	65·9	14·0	16·1	96·0	17·02	2·17
TIBA 10 μgm.	70·9	19·3*	15·0	105·2	14·64	2·42
GA 10 μgm.	95·8*	22·6*	19·0	137·5*	13·89	2·67

* Significant at $P = 0·05$.

TIBA, 2,3,5-triiodobenzoic acid; GA, gibberellic acid associated with the juvenile leaf form in *Ipomoea*[6]. Allsopp[7], discussing the effect of growth substances on heteroblastic development, suggests that the mechanism of the action of these substances in delaying the onset of the adult leaf form is through their effect in diverting nutrients from the apex to other organs thereby producing changes in the shoot–root ratio, generally inhibiting growth and depressing the activity of the apex. In *Ipomoea*, however, both 2,3,5-triiodobenzoic acid and gibberellic acid treatment increase shoot growth and leaf production, indicating increased rather than decreased activity of the apex. But there is a relative depression of root growth. Whether this reduced root growth has a causal relation to leaf form, for example, by bringing about a deficiency of phyllocaline or some other substance produced by the roots as suggested by Audus[8], requires further investigation.

Occurrence of Gibberellin-like Substances in the Coconut

COCONUT milk contains substances which promote the growth of plant tissue cultures and isolated embryos. Some of these have been isolated[1,2] and one has been shown to be 1 : 3-diphenylurea[3]. Mauney *et al.*[4] have found a growth-factor which is mainly in the flesh of the coconut.

Substances which are physiologically gibberellin-like, in so far as they promote increased growth of genetic dwarfs of some plants, have been found in the immature seeds of a number of species of plant[5]. One of these has been identified[6] as gibberellin A_1. Experiments are described below which indicate that gibberellin-like substances occur in milk, flesh and embryos of the coconut. The growth-promoting properties of coconut milk may well be in part due to such materials.

Coconut milk was acidified to *p*H 2·5 and was stirred with activated carbon (20 gm./l.). The carbon was eluted with 70 per cent acetone. The acetone was then distilled off *in vacuo*, and the aqueous residue acidified and extracted with ethyl acetate. The ethyl acetate was dried and distilled off, and the residue was dissolved in ethanol and spotted on chromatography paper. Chromatograms were run in the following solvent system : chloroform/water/ethanol/formic acid (20 : 2 : 4 : 1). A chromatogram run from one spot was tested for gibberellin-like activity by the use of the wheat leaf section test[7]. Using this as a guide, the presumed active part of the main chromatogram was eluted with water and this was extracted with ethyl acetate. The eluate was concentrated and applied to the leaves of intact dwarf peas in ethanol.

The solid endosperm was macerated in a blendor with carbon tetrachloride to remove most of the oil. The solvent was filtered off, and the solid material was extracted with ethanol at room temperature overnight. The endosperm was filtered and pressed, and the ethanol solution was distilled *in vacuo*. The aqueous residue was filtered, acidified to *p*H 2·5 and extracted with ethyl acetate. The acid fraction was removed with 1 per cent sodium bicarbonate solution, which was acidified and extracted with ethyl acetate. This was concentrated and chromatogrammed as in the case of the milk. In this experiment the whole chromatogram was eluted in two parts, as the activity appeared to be spread over a large area.

The solidified coconut oil remaining when the carbon tetrachloride had been distilled off was stirred with water. The fat was filtered off after chilling. The water was then treated in the same way as the aqueous residue in the experiment described above.

Embryos found in some of the coconuts were extracted like the solid endosperm.

Table 1. GROWTH-RATE OF 'METEOR' PEA SEEDLINGS EXPRESSED AS PERCENTAGE OF THAT OF UNTREATED SEEDLINGS, AFTER APPLICATION OF EXTRACTS OF COCONUTS

Substance extracted		Fresh weight equiv. (gm.) of extract applied to each test plant	Days after treatment

Milk		188*	192	225	220	109	

* ml. of coconut milk.

The results given in Table 1 show that gibberellin-like activity was found in all parts of the coconut. The activity of the milk extracts cannot be directly compared with that from the meat, as a different sample of nuts was used. The activity of the extract of the embryos was remarkably high and needs to be confirmed ; this will be done when more coconut embryos are available. The nuts used in these experiments were fairly mature with a high proportion of solid to liquid endosperm. It is possible that younger nuts would contain more gibberellin-like activity, for whereas the embryos seem to contain an amount of gibberellin-like substances of the same order as young bean seeds[6], the endosperm contains much less, while in bean seeds the activity is distributed more or less evenly through all the tissues of the seed[7].

Nitrate Content of some Grass Species and Strains

In the course of an investigation into possible sources of error in the determination of crude protein in herbage by the conventional method, a number of determinations of nitrate nitrogen were made. It is customary in this laboratory to use a reference herbage sample as a check in the routine. The nitrate nitrogen in this was determined first and found to be approximately 0·1 per cent. The reference sample is bulked from a large number of herbage samples, mainly grass, which pass through this laboratory. A nitrate content of this magnitude is therefore an average figure for several hundred samples and implies that some of the herbage which contributed to the reference sample may have contained considerable (possibly even nutritionally unacceptable) amounts of nitrate nitrogen.

Several grass samples which might be expected to show extreme amounts of nitrate nitrogen were selected for determination from an experiment in which eight species and strains of grasses grown as spaced single plants and in swards had been heavily manured with nitrogen. Samples were taken of the growth at successive dates for nitrate nitrogen determination. The results are given in Table 1. It is to be noted that the figures for each date represent the composition of the total growth of the herbage up to that date and not of regrowth after successive cuts.

Since an accumulation of mineral nitrogen must be regarded as being in excess of the plant's immediate needs or ability to use, the generally higher nitrate content of the spaced single plants is to be expected, as there would be less inter-plant competition for nitrogen than in the swards; the single plant plots had received the same dressing of nitrogen per unit area as the swards. It will be seen also that their total nitrogen, without exception, is substantially higher.

At the fourth and fifth dates of cutting the sward plants show nitrate contents similar to those of the spaced plants at the same dates. The fourth cutting date was only eight days after a dressing of nitro chalk, but at the fifth date, a fortnight later, there

Figures in brackets are crude protein (N × 6·25).

was still a substantial residue of nitrate. The effect of the manurial dressing on the nitrate nitrogen of the swards is greater at the fourth and fifth dates than at the second and third, presumably owing to the slower growth and decreased metabolism of nitrogen at the later dates, which fell in a rather dry period, having only 0·92 in. of rain between June 10 and July 7, 1957. This is consistent with the finding of Ferguson and Terry[1] that applications of nitrogen late in the growing season resulted in increased amounts of nitrate nitrogen in the herbage.

It is to be noted from the results that a high total nitrogen is not necessarily a prerequisite for a high nitrate nitrogen content. A high nitrate, however, seems to be associated with a generally lower proportion of true protein nitrogen to total nitrogen.

The main interest of the present results, however, lies in the species and strain differences. In the spaced single plants, *S*23 perennial ryegrass and *S*143 cocksfoot are almost without exception considerably higher in nitrate than the remaining grasses. In the swards, however, *S*24 ryegrass has a considerably higher nitrate content than *S*23, while *S*143 cocksfoot no longer heads the list and in the last two cuts of the swards has actually the lowest nitrate content.

No attempt is made at this stage to offer any explanation of these species and strain differences in nitrate accumulation. The investigation continues and the results will be published elsewhere in due course.

Acknowledgment is made to Mr. Ll. Iorwerth Jones, who provided the material for analysis from a field experiment at this Station.

A Direct-Plating Method for the Assay of Radioactive Isotopes in Aqueous and Alcoholic Samples

In the course of a programme of work on the determination of residue levels of γ-2 : 4-dichlorophenoxybutyric acid and related compounds in plants, the results of which will be reported in the Proceedings of the British Weed Control Conference, 1958, a rapid method was required for the radiochemical assay of non-volatile compounds labelled with carbon-14 contained in aqueous and alcoholic solutions.

A method for plating aqueous samples in which the compound to be assayed is incorporated into a film of dry agar has been published by McCready[1]. We are grateful to Dr. McCready for having described to one of us (H. C.) the basic principles of his method before publication. A modification of the method has proved to be free from complications due to coagulation of the agar when alcoholic solutions are to be assayed and a sample can be prepared for counting within 20 min. The precision, although not as high as that obtained by McCready, is adequate for many purposes, and this limitation is offset by the speed and convenience with which samples can be prepared for counting.

A measured volume of 0·1 per cent aqueous solution of agar is pipetted on to a planchette which has been washed with carbon tetrachloride. An equal volume of the aqueous or alcoholic solution of the sample to be counted is added and mixed by stirring with a fine wire. It is convenient to take a volume of 0·1 ml. of each solution when using a planchette 15 mm. in diameter and 2 mm. deep. The planchette is then placed on a hot plate at about 60° C. and allowed to dry; the thin film should be invisible.

When an end-window Geiger–Müller tube type *EW.3H* (20th Century Electronics, Ltd.) was used the count-rate per μgm. given by a sample of an organic acid of molecular weight 217 labelled with carbon-14 at specific activity of 0·46 mc./m.mole was 235 c.p.m. above background, that is, the counting efficiency was about 5 per cent. The precision of the method, tested by carrying out ten replicate determinations on samples of a solution containing carbon-14, was ±1·5 per cent under conditions where the statistical variation in counting should not have exceeded ± 0·6 per cent.

We thank Miss G. Mansfield for carrying out thorough independent tests of the technique, and the Directors of Messrs. May and Baker, Ltd., for permission to publish.

Relationship of Serological Reactivity to Antibody Molecular Weight

In recent years information has been obtained concerning the molecular weight of antibody in relation to specific serological reactivity. Deutsch and Chan[1] found that human A and B *iso*agglutinins have molecular weight near 1,000,000. Paic[2] reported that rabbit anti-sheep hæmolysin had a minimum molecular weight of 420,000. More recently, Talmage *et al.*[3] found that the hæmolytic activity of rabbit anti-sheep hæmolysin was associated with antibodies of two distinct molecular weights. The bulk of the hæmolytic activity was associated with a high molecular weight antibody of greater hæmolytic efficiency and in addition a low molecular weight antibody of lower hæmolytic efficiency. Johnson *et al.*[4] reported that rabbit anti-human hæmolysin, in contrast to rabbit anti-sheep hæmolysin, has a molecular weight in the region of 160,000. We observed[5] that human anti-A and rabbit anti-human hæmolysin had the same complement-fixing capacity (the amount of complement capable of being fixed), while rabbit anti-sheep hæmolysin had a complement-fixing capacity 3–4 times lower.

On the basis of the above information and the comparison of the sedimentation characteristics of the agglutinin, hæmolysin and complement-fixing activities of human anti-A, rabbit anti-human and rabbit anti-sheep erythrocyte antibodies, we wished to determine the association of serological reactivity to antibody molecular weight.

Centrifugation was carried out in a 'Spinco' Model *E* ultracentrifuge. The sera were initially diluted 1 : 4 with veronal buffered saline *p*H 7·4. 11 ml. of the diluted serum was centrifuged 200 min. in an average field of 102,750*g*. Fractions were taken from the top, middle and bottom of the tube in 4, 4, and 3 ml. amounts. The agglutinin, hæmolysin (H_{50} units/ml.) and complement-fixing ($C'F_{50}$ units/ml.) titres were determined as previously described[5,6].

The results presented in Table 1 indicated that: (1) There was an association of hæmolysin and complement-fixing activities with antibodies of similar molecular weight, in human anti-A and rabbit anti-human serums, as shown by the consistency of the ratio of $H_{50}/C'F_{50}$ titres in the whole serum and the various fractions. (2) The $H_{50}/C'F_{50}$ ratio of rabbit anti-sheep serum did not show this consistency and indicated a closer association of hæmolytic activity with higher molecular weight antibodies and complement-fixing activity with lower molecular weight antibodies. (3) Both hæmolysin and complement-fixing activities of human anti-A serum appear to be attributable to antibodies of low molecular weight, as judged by the similarity in the relative hæmolytic activity of the fractions of rabbit anti-human serum which has been found to be of low molecular weight[4]. (4) The hæmolytic activity of human anti-A antibodies which cross-react with sheep cells were of very high molecular weight, as shown by the fact that 70 per cent of this antibody was found in the bottom fraction. (5) The comparison of the relative agglutinin activity in the fractions of each serum indicated that this activity in all three serums was associated with antibodies of high molecular weight.

Table 1. RELATIVE ANTIBODY ACTIVITY IN ULTRACENTRIFUGE FRACTIONS

Fraction	Titres			Ratio: $H_{50}/C'F_{50}$	Relative activity from top to bottom		
	Agglu.	H_{50}/ml.	$C'F_{50}$/ml.		Agglu.	H_{50}	$C'F_{50}$
Human anti-A and A cells							
Whole	128	5·8	5·2	1·1	—	—	—
Top	32	2·4	2·1	1·1	1	1·0	1·0

Rabbit anti-sheep and sheep cells							
Whole	128	2,940	435	6·8	—	—	—
Top	32	926	175	5·3	1	1·0	1·0
Middle	64	1,850	328	5·6	2	2·0	1·9
Bottom	256	6,190	910	7·6	8	7·5	5·2
Cross-reaction of human anti-A and sheep cells							
Whole		16·0					
Top		1					
Middle		6·1					
Bottom		42·0					

The complement-fixing activity of rabbit anti-sheep serum was associated with antibody of low molecular weight, unlike the bulk of the hæmolytic activity, which was represented by high molecular weight antibody. However, a comparison of the complement-fixing capacity of these fractions showed no change in the amount of complement capable of being fixed by the various fractions in spite of differences in the ratio of high and low molecular weight antibodies occurring in the fractions.

In contrast to the normal human *iso*agglutinins and similar to the human 'incomplete' Rh antibodies[1], human *iso*hæmolytic and complement-fixing activities were associated with antibodies of low molecular weight. The serological reactivity of rabbit anti-human serum was quite similar: agglutinin activity was associated with high molecular weight antibody and hæmolysin and complement-fixing activities were associated with lower molecular weight antibody.

Further β-Globulin Phenotypes in Sheep

IN a preliminary communication eight sheep β-globulin types were described[1]. This number has now been increased partly by recognition of the fact that the two strongly staining zones *C* and *D* can be resolved into a third zone, and partly by the discovery of further types during examination of five hundred samples of sheep serum from Chelmsford abattoir.

The fourteen phenotypes which have been found so far (Fig. 1) probably represent the ten heterozygotes, and four of the five homozygotes of five β-globulin alleles, sheep β^A, β^B, β^C, β^D and β^E.

In keeping with the phenotype nomenclature suggested for the cattle[2] and goat[3] β-globulin systems, the phenotypes have been named sheep β^{AA}, β^{AB} . . . β^{EE}, representing the individual genotypes β^A/β^A,

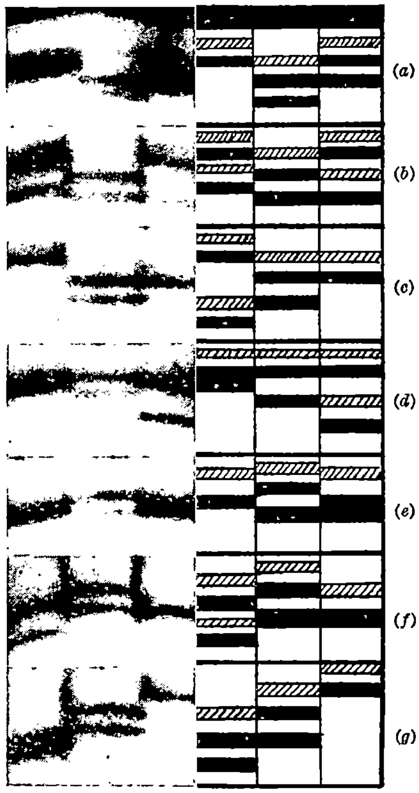

Fig. 1. Fourteen sheep β-globulin phenotypes. The illustration shows the β-globulin region of seven starch-gel electropherograms, each gel carrying three sera. The phenotypes are, from left to right on each gel, (*a*) β^{AA}, β^{BD}, β^{AB}; (*b*) β^{AC}, β^{BD}, β^{AD}; (*c*) β^{AE}, β^{BD}, β^{BB}; (*d*) β^{BC}, β^{BD}, β^{BE}; (*e*) β^{CC}, β^{BD}, β^{CD}; (*f*) β^{CE}, β^{BD}, β^{DD}; (*g*) β^{DE}, β^{BD}, β^{AA}. The trailing edge of the albumin zone is shown at the top of gel (*a*) for orientation

β^A/β^B, . . . β^E/β^E. So far the homozygote β^{EE} has not been found.

Each allele produces two zones in starch gel, an intensely staining zone preceded by a less intensely staining zone[3] (Fig. 1). In types involving combinations of β^B, β^C and β^D, the fainter zones are not seen because of the superimposition of the intensely staining zones. Distinction between the sheep β-globulin types is best made by reference to a β^{BD} serum run on the same gel.

120 different matings are possible with the five-allele system proposed. Some of the mating data obtained so far (from the Kerry Hill flock at the Farm Livestock Research Centre) is shown in Table 1.

Table 1. β-GLOBULIN MATING RESULTS FROM EWES MATED WITH A β^{BB} RAM

Mating	Phenotype of offspring				
	AB	*BB*	*BC*	*BD*	*BE*
BB × *AB**	2	2	-	—	—
BB × *AD*	0	—	—	1	—
BB × *AE*	0	—	—	—	2
BB × *BB*	—	1	—	—	—
BB × *BC*	—	5	2	—	—
BB × *BD*	—	0	—	2	—
BB × *BE*	—	0		—	1
BB × *CC*	—	—	1	—	—
BB × *CD*	—	—	2	5	—
BB × *CE*	—	—	2	—	0
BB × *DD*	—	—	—	1	—

* *AB* is equivalent to β^{AB} and so on.

Sheep exhibit the most complex example of β-globulin polymorphism found so far, although it is now known that β-globulin polymorphism in mammals is the rule rather than the exception.

I thank K. F. Mitchell for his technical assistance.

Hageman Factor in Plasma Foreign Surface Reactions

PLASMA kinin[1] (originally named "pain-producing substance"[2]) is a pain-producing and smooth muscle-contracting polypeptide which can be released from human blood plasma in a number of ways, including contact with glass and some other surfaces. The mechanism of kinin release by contact has been resolved into two stages: in the first, 'contact factor' is formed from its precursor ('component *A*'); in the second 'contact factor' reacts with another constituent ('component *B*')[1,3].

Plasma can be freed of component *B* by rotating for 5 min. with 1/7–1/5 gm./ml. of glass ballotini (diameter 0·1 mm.) and then incubating in siliconed tubes for 2 hr. Such '*B*-depleted' plasma does not release any kinin on contact with glass but can still form 'contact factor' which will liberate the kinin when mixed with untreated plasma. Further exposure to 1 gm./ml. of ballotini for 30–60 min. exhausts the capacity of plasma to form the 'contact factor', presumably because its precursor (component *A*) has been used up[1,3].

'Contact factor' cannot be produced in plasma deficient in Hageman factor[4], which is also essential for the initiation of clotting *in vitro*[4,5]. On this ground and because of many other similarities with the changes involved in the inception of clotting, it was suggested that these two sets of phenomena are mediated by a common initial reaction[1,3].

In the present experiments it was found that although neither Hageman-deficient plasma nor plasma depleted of component *A* could form contact factor, a mixture of the two behaved like normal plasma. The mutal correction occurred only if the two plasmas were exposed to glass together, but not when they were exposed separately and mixed afterwards. It follows that component *A* is not identical with Hageman factor, and probably also that one of these components is active only when in actual contact with the surface.

The following observations indicate that Hageman factor becomes activated by adsorption on to the glass surface and that it does not return into solution in the active form as was previously thought. When glass was treated with normal plasma, it acquired the ability to activate fully Hageman-deficient plasma. This property persisted after washing with ten or more changes of saline at *p*H 7–8. Prior treatment of glass with Hageman-deficient plasma had no such effect. The adsorbed substance could be eluted at *p*H 10–11 and, after addition of sufficient hydrochloric acid to lower the *p*H to about 8, could be transferred on to fresh glass. At the same time the glass which was washed in the alkaline solution lost its ability to react with Hageman-deficient plasma, but it could still activate normal plasma. Since the addition of the eluate (without glass) to normal plasma did not lead to kinin release, it appears that the adsorbed component (presumably Hageman factor) reverts to its precursor state when removed from the glass surface.

Parallel observations were recorded on the behaviour of Hageman factor in blood coagulation, in this case plasma thromboplastin antecedent taking part instead of component *B* in the corresponding stage of the reaction[5]. All the evidence thus leads to the conclusion that release of plasma kinin and initiation of clotting are connected through surface-adsorbed Hageman factor. The kinetics of the initial stages of kinin release and coagulation can be appreciated better if we think of Hageman factor activating the glass surface rather than the other way round.

Since the similarities between the two sets of phenomena can now be explained on this basis it is no longer necessary to postulate another connexion between them, although this is by no means excluded. In previous publications[1,3] such a connexion was attributed to a common 'contact factor', which was implicitly defined as the first observable soluble product of the contact reaction. If this meaning is to be preserved then the precursor of 'contact factor' cannot be identified with Hageman factor but must be regarded rather as a substrate on which the latter acts. It is conceivable that there exist in plasma two or more 'contact factor' systems activated by the same initial reaction in which Hageman factor is the key component.

The present conclusions are supported by the studies of Bangham *et al.*[6], who showed that glass particles coated by plasma proteins exhibit marked changes in their electrophoretic mobility. Above *p*H 9 the mobility tends to revert to that of uncoated glass, probably due to desorption of the adsorbed proteins.

It is unlikely that Hageman factor is the only component of plasma which adheres to the glass, but it should be possible to make use of this property as a step towards its isolation.

The full details of this investigation will be published elsewhere.

I wish to thank Prof. C. A. Keele for his valuable advice, Dr. R. M. Hardisty for samples of plasma, and Mr. F. J. Haydon and Miss B. Austin for technical help.

The work was pursued under tenure of an Australian and New Zealand Life Insurance Medical Research Fellowship.

A Rapid Method for separating Glomeruli from Rabbit Kidney

In the course of investigations into the site at which renin is found in the kidney it became necessary quickly to separate glomeruli from other renal elements. Previous experiments on fat embolism had shown that in the kidney fat particles were restricted largely to glomeruli. It therefore seemed possible that if particles of the right size could be introduced into the renal circulation they would lodge in the glomeruli. This consideration, together with an early admiration for the experiment in which the function of the otocyst and otolith were demonstrated by inducing the crayfish (*Palinurus*) to use a particle of magnetic oxide of iron as an otolith, suggested that if the particles introduced into the renal circulation were magnetic it would be possible to separate the glomeruli with a magnet. This has been done. Since it can be done quickly and without much greater disturbance than is involved in mechanically disrupting the kidney, the method may be useful to others interested in locating enzymes in the kidney.

Heparin (1,000 units) is injected intravenously in a rabbit. Five minutes later the animal is killed. After death the abdomen is opened and the renal arteries cannulated, care being taken to avoid introducing air bubbles. The cannulæ are connected to an infusion apparatus containing a freshly prepared warm (37° C.) suspension of magnetic oxide of iron in 0·9 per cent sodium chloride. The infusion is allowed to run in under a pressure of 120 mm. mercury until about 100 ml. has flowed through each kidney and the rate has greatly slowed. The kidneys are then excised and taken to a laboratory at 4° C. at once. The magnetic oxide of iron was prepared by the method of Baudisch and Welo (1925) in which 2·6 gm. sodium hydroxide and 20 gm. potassium nitrate dissolved in about 100 ml. of water saturated with oxygen are poured into a solution of 9 gm. ferrous sulphate in about 100 ml. of water and the mixture brought to the boil. The precipitate of magnetic oxide of iron is now particulate and is washed about ten times with water by decantation. It is kept in 0·9 per cent sodium chloride until it is needed. Just before the rabbit is heparinized the iron oxide suspension is added to a freshly prepared filtered warm solution of 7 per cent gum acacia in 0·9 per cent sodium chloride, the concentration being about 50 mgm. dry oxide for 100 ml. solution.

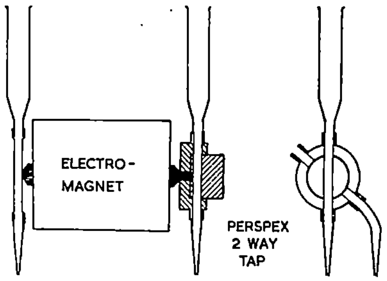

Fig. 1. Arrangement used for magnetic separation

The kidneys are cut into transverse sections about 2 mm. thick. The glomeruli should be visible as black specks, and cleared sections show that the iron particles are largely restricted to the glomeruli, though some medullary vessels contain them. The cortex is now cut off with a razor blade, the resulting fragments of cortex are pressed through a 150-mesh sieve and the mush emerging on the other side suspended in isotonic physiological salt solution containing 2 gm. dextrose and 4·5 gm. sucrose per litre[1]. Although in our work we have used this formula for physiological saline, Krebs's solution would for most purposes be preferable. The suspension is centrifuged slowly (800 r.p.m.). The deposit is resuspended in fresh saline solution and again centrifuged. The deposit, again suspended in saline solution, is now poured slowly through a tube, or system of tubes, which at one point lies close to the pole of an electro-magnet consisting of 10 lb. of 18 S.W.G. enamelled copper wire wound on a soft-iron core and connected to a 12-V. accumulator (Fig. 1). Attached to one pole of the magnet is a 'Perspex' two-way tap (Fig. 1, right). The first separation is made by running the suspension through one system of tubes, physiological saline succeeding the suspension to carry away non-magnetic particles. Afterwards the tap is turned, the magnet switched off and the magnetic fraction now adhering to the 'Perspex' tap in apposition to the magnet washed off through the second system of tubes with physiological saline. The separation, using this system, is repeated two or three times. The final purification is made by running suspensions through a vertical tube, of which the centre section consists of a thin-walled rubber tube touching the other pole of the electro-magnet. After washing the adherent magnetic fraction with physiological saline, this section of tubing is removed and the glomeruli washed out.

The magnetic and non-magnetic fractions so obtained are run past the magnet until examination under the microscope shows that all, or nearly all, the magnetic fraction consists of tissue containing iron, while the non-magnetic fraction contains none (Fig. 2). At this stage the magnetic fraction consists of glomeruli with or without attached fragments of

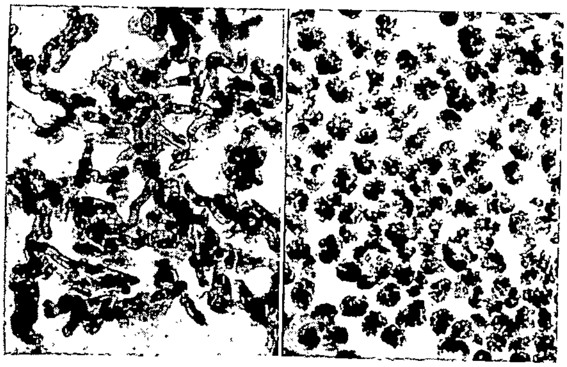

Fig. 2. Photographs (×80) of non-magnetic fraction on left and magnetic fraction on right. The magnetic fraction consists entirely of glomeruli containing iron oxide, some of the glomeruli having attached fragments. The non-magnetic fraction consists mainly of tubules, though connective and vascular tissue and a few fragments of glomeruli without iron are present

proximal tubules, macula densa and arterioles. By pouring this fraction through a 150-mesh sieve it may be separated into glomeruli without attachments, which pass through, and those with attachments, which remain on top. The non-magnetic fraction consists almost entirely of tubules, though there are often small fragments of glomeruli without iron as well as vascular and connective tissue.

The method was devised to locate renin, for which it has proved helpful. We have also used it successfully in the sheep and see no reason why it should not be applicable to other species. It is presented here in the hope that it may help those who are interested in the distribution of enzymes and other substances and who wish to decide whether they are found in glomeruli or tubules.

Maintenance of Oligotrich Protozoa from the Sheep Rumen *in vitro*

HUNGATE[1,2] successfully cultivated ciliate oligotrich protozoa from the rumen of cattle; but Sugden[3] was unable to maintain protozoa from the sheep's rumen alive for more than fifteen days. This communication describes the successful maintenance of these protozoa from the rumen of a single hay-fed Clun Forest sheep.

The substrate consisted of 30 ml. quantities of autoclaved mineral salt solution to which was added: $Na_2S.9H_2O$ to a final concentration of 0·01 per cent; *c.* 15 mgm. finely ground dried grass (55° for 3 days); 15 mgm. rice starch, added as a suspension of known concentration in water; chloramphenicol to a final concentration of 50 µgm./ml. and 3·0 ml. prepared rumen fluid. The final volume was *c.* 35 ml. The mineral salt solution contained per 100 ml.; K_2HPO_4, 0·63 gm.; KH_2PO_4, 0·49 gm.; NaCl, 0·063 gm.; $MgSO_4.7H_2O$, 0·009 gm.; $CaCl_2.6H_2O$, 0·009 gm.; CH_3COONa, 0·075 gm. The rumen fluid was taken from the same sheep as the original inoculum and prepared by centrifuging fresh crude rumen contents to remove protozoa followed by filtration through Ford's 'Sterimat *CC*/01'. Tubes of completed medium were gassed vigorously with 95 per cent nitrogen + 5 per cent carbon dioxide for 3 min. and stoppered immediately.

The protozoa for inoculation were prepared from rumen contents taken 3–6 hr. after feeding. The crude material was strained through one layer of muslin, centrifuged for 2 min. at 500*g* and the pellet washed once on the centrifuge with the salt solution containing 0·01 per cent $Na_2S.9H_2O$. The protozoa were then suspended in the medium at 2–4 times their concentration in the rumen and the tubes gassed for 15 sec., stoppered immediately and incubated at 38°. In the initial stages of each experiment, it was beneficial to add 15 mgm. $MgCO_3$ levis to each tube, but when the organisms were growing uniformly this could be omitted.

To maintain the organisms alive for more than 36 hr., it was necessary each day to centrifuge down the protozoa at 500*g* for 2 min., remove the supernatant and replace this by fresh complete medium. To divide a culture, the protozoa suspended in the fresh medium were diluted with an equal volume of complete medium and the whole placed in two centrifuge tubes which were then gassed and sealed. The number of organisms present was estimated by diluting a sample of the culture eleven times with 0·02 *M* iodine in potassium iodide and counting the protozoa present in 0·1 ml.

After the initial inoculation, the total number of organisms decreased and all the holotrich protozoa died before the fifth day. Thereafter, the number of oligotrich protozoa remained constant or slowly decreased for 2–8 weeks after which the numbers increased. When the number of organisms reached 30,000 per ml. the culture was divided into fresh medium. The numbers increased until it was possible to divide the culture into fresh medium every 2–4 days, and at the time of writing, the maximum number of such divisions was 40. A typical growth curve from this last period is shown in Fig. 1.

The predominant types of organisms were morphologically similar to *Entodinium caudatum* and *E. longinucleatum* as described by Bhatia[4], but some similar to *Metadinium medium* and *Entodinium simplex* were also present, especially when the time between successive divisions exceeded 10 days.

Under these conditions of growth, the omission from the medium of the rice starch or dried grass usually resulted in the death of the protozoa in less than

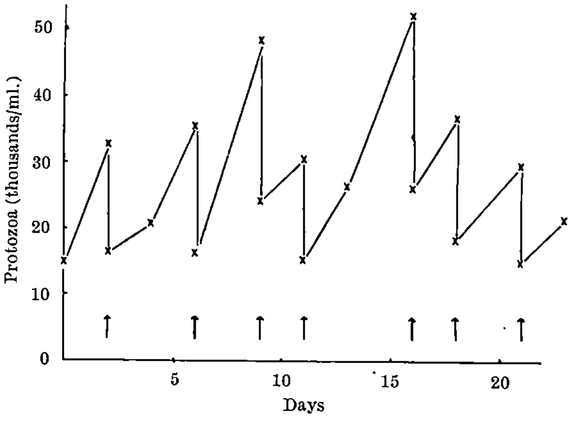

Fig. 1. Growth of oligotrich protozoa four months after the initial inoculation. The arrows indicate the times at which the culture was divided into an equal volume of fresh medium

3 or 10 days respectively, although, in the latter case, small numbers occasionally persisted for longer periods. When chloramphenicol or rumen fluid were omitted, the organisms grew normally for 3–4 days, but afterwards the numbers dropped to, and remained constant at, a low level. Sterilization of the dry rice starch at 140° C. for 1 hr. and heating the dry grass at 100° C. for 2 hr. prior to addition to the medium did not affect the growth-rate. No organisms were found after one week in uninoculated control tubes.

Further experiments are at present in progress in an attempt to increase the growth-rate of the organisms and to isolate a single strain of protozoan.

I wish to thank Miss C. M. Tebbutt for her expert technical assistance.

Sodium Uptake by the Crayfish

It is now well established that many freshwater animals can absorb sodium and chloride ions from very dilute solutions. This was first demonstrated by Krogh[1] in animals which had been previously depleted of salt; since then, it has been shown by the use of radioactive tracers that in the axolotl[2], in the frog[3] and in the crab, *Eriocheir*[4], ion absorption occurs continuously in the normal animal as part of the mechanism for the maintenance of salt balance. Salt balance results when the rate of salt uptake equals the total loss of salt through the integument and by way of the excretory fluid, but little is known of the extent to which the uptake rate is regulated by the animal or of the internal or external factors upon which the uptake rate normally depends.

An attempt has been made to throw some light on the mechanism of the regulation of sodium uptake in the freshwater crayfish, *Astacus pallipes*. In particular, the influence of variations in the internal sodium content and of the external sodium concentration on the rate of uptake, has been studied.

To measure sodium uptake, a crayfish weighing about 10 gm. was placed in 250 ml. of water containing a known concentration of sodium chloride in the range, 0–1 m*M*/l. A proportion of the added sodium was present as sodium-24 and the radioactivity of the solution was measured initially and then at frequent intervals after the start of the experiment. No experiment proceeded long enough for back-diffusion of radiosodium to have a significant effect on the measured uptake rate or for large changes in the internal or external sodium concentrations to occur. The rate of uptake of sodium (the sodium influx) was calculated from the rate of loss of activity from the outside solution, after correction for decay. Net uptake was also measured from changes in the external sodium concentration.

The normal uptake rate for animals in 0·3 m*M*/l. sodium chloride solution (the sodium concentration of Newcastle tap-water) was about 1·5 μ*M*/hr./10 gm. body-weight (Table 1). Loss of sodium from the animal caused a gradual increase in the uptake rate until a maximum rate for a given external concentration was reached (Table 1). The maximum rate was 4–5 times the normal value. Conversely, sodium uptake was depressed by an increase in the internal sodium. When the uptake mechanism was stimulated the animal could maintain itself in sodium balance at a much lower external sodium concentration than before (Table 1). At the maximum uptake rate the equilibrium concentration was only about one-tenth of the normal tap-water concentration. To increase the uptake rate from normal to the maximum required the loss of about 6–8 per cent of the internal sodium. Significant changes in the uptake rate occurred after changes of only 1–2 per cent of the internal sodium content.

Table 1. Uptake Rates in the Crayfish, measured with Sodium-24

Specimen No.	Uptake rate from 0·3 m*M* NaCl sol. in μmole/hr./10 gm. body-weight Normal rate	Maximum rate	Lowest equilibrium concentration m*M* Na
1	1·1	5·3	0·03
2	1·4	4·9	0·03
3	1·7	5·7	0·09
4	1·8	7·3	—
5	1·4	5·3	0·02
6	1·5	7·8	0·04

The low equilibrium concentration achieved when the uptake rate is maximal is a direct consequence of the fact that the uptake rate, itself, depends on the external sodium concentration. The relationship between these for a typical individual is shown in Fig. 1. This shows the uptake rates for the animal in equilibrium with an external concentration of 0·2 m*M*/l. sodium (open circles) and also the increased uptake rates of the animal in equilibrium with an outside concentration of 0·03 m*M*/l. sodium (full circles). The relation between the uptake rate and the external sodium concentration is a non-linear one but appears to conform to a relation of the Michaelis–Menten type, as might be expected if the sodium ions are transported by a carrier system which becomes saturated at higher sodium concentrations. The continuous line in Fig. 1 is derived from the expression: $M = Kc/(K_m + c)$, where M is the uptake rate and c the external sodium concentration. The constants, K and K_m have been given arbitrarily chosen values of 7 and 0·25 respectively. The very low concentration at which half-saturation occurs is noteworthy and indicates a very high affinity of the carrier for sodium ions.

These studies show that sodium uptake in the crayfish takes place by a mechanism which is highly regulated and well adapted to maintain the animal

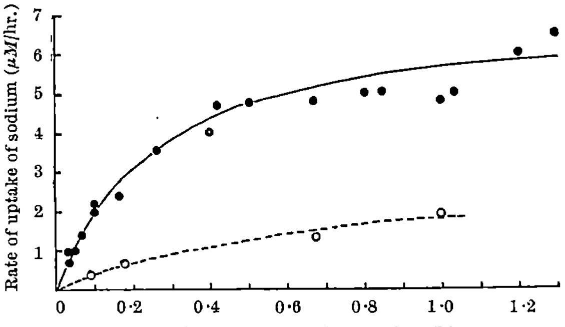

Fig. 1

in sodium balance. Although the rate of uptake is sensitive to changes in the external sodium concentration (at the concentrations found in tap-water) any resulting change in the internal sodium content brings about a change in the uptake rate in the opposite direction and a self-balancing system results.

Prevention of Allergic Encephalomyelitis by Prior Injection of Adjuvants

In a recent article[1] Svet-Moldavskaya and Svet-Moldavsky have reported that repeated injections of immature rabbit brain into guinea pigs prevented the development of allergic encephalomyelitis when the same animals were given active (adult rabbit brain) injections at a later date. From this observation they have proposed the existence in brain of two factors, one of which is responsible for the development of encephalomyelitis, the other for the development of acquired resistance against it.

The acquired resistance to allergic encephalomyelitis described by these authors has been observed previously, but it was not ascribed to any factor in brain itself. Lumsden first described it in 1949 [2] and rightly attributed protective action of inactive brain fractions to the adjuvant itself. He states: "The results . . . seem to suggest that the mere injection of 'adjuvants' alone may in some way produce immunity to the encephalitogenic factor in brain tissue".

Results obtained in our laboratory have verified Lumsden's assumption (Table 1). The animals in experiment *A* were given as their first injection the complete vaccine, as controls for subsequent tests on protection. Since they all succumbed to the disease, no challenge injection was possible. In experiment *B* three different initial injections were given, each containing one of the ingredients of the complete vaccine (oil/aquaphor, bovine cord fraction, and killed tubercle bacillus). The complete vaccine was injected thirty days after the initial injection. Of these three, the killed tubercle bacillus was the only one showing any protective effect. From experiment *C* it is apparent that the oil–aquaphor component, inactive in suppressing subsequent disease when injected alone, markedly enhances the protective effect of the tubercle bacillus. The nervous tissue fraction in oil/aquaphor also appeared to have a slight protective effect, but the difference is not significant at the 5 per cent level. Killed tubercle bacillus and nerve fraction combined may be somewhat more effective than tubercle bacillus alone, but this is doubtful.

Histological examination of the inoculation sites of those animals receiving a primary protective injection (killed tubercle bacilli in oil-adjuvant mixture) revealed almost complete suppression of epithelioid cell reaction and encapsulation of the injection material by neutrophilic leucocytes and fibrous tissue, compatible with the Koch reaction.

Table 1. PROTECTION AGAINST ENCEPHALOMYELITIS BY PRIOR INJECTION WITH INCOMPLETE VACCINE

Expt.	Composition of first vaccine*			Disease index† (mean ± S.E.)
	Oil + aquaphor (ml.)	Bovine cord fraction (mgm.)	Tubercle bacilli (mgm.)	
A	0·08	0·02	0·25	7·9 ± 1·2‡
	0·08	0·02	0·25	8·4 ± 0·9‡
	0·08	0·02	0·1	7·1 ± 1·1‡

	—	0·02	0·25	1·1 ± 0·3
	—	0·02	0·25	0·1 ± 0·03§
	—	0·02	0·1	6·0 ± 1·8
	0·08	—	0·5	0 ± 0
	0·08	—	0·25	0·2 ± 0·1
	0·08	—	0·1	0 ± 0
	0·08	—	0·01	1·2 ± 0·7

* Given 30 days prior to complete vaccine.

† Measure of severity of disease reaction based on clinical and histological results. 0 = no reaction; 10 = maximal reaction in all animals on test (ref. 3).

‡ Complete injection, no challenge possible.

§ No challenge given, killed at 60 days.

Protection against 'allergic' encephalomyelitis is complex and may be produced in many different ways[4]. It can be produced by a single injection of a saline suspension of brain in neonatal or immature animals (see Paterson[5], also discussion by Waksman) by repeated injections of brain in adult animals (Ferraro, Condie[5]), or by passive transfer of serum from encephalitic animals (Florey[5]) and by other techniques, such as reported here.

It should be noted that in the present experiments only a single injection of incomplete vaccine was given one month before challenge, that the most important protective factor under these conditions is in the tubercle bacillus, and that this factor is markedly potentiated by the oil–aquaphor suspending medium. The data do not preclude the possibility that repeated injections of brain in oil–aquaphor might produce significant protection, but this experiment has not yet been performed. Whether there would be any difference between immature and mature brain in such an experiment also remains to be determined. However, since the results of Svet-Moldavskaya and Svet-Moldavsky can be attributed to the presence of tubercle bacillus in the original injection, their conclusions regarding a protective factor in immature brain are unjustified until the latter is tested in the absence of tubercle bacillus.

Movements of Lugworms

A RECENT review of the hydrostatic skeleton in invertebrates by Chapman[1] includes the following sentence about *Arenicola*: "Wells (1954) has shown that the three anterior septa are connected with the retention of the proboscis against the normal resting or tonus pressure maintained by the body-wall in the cœlom, which would otherwise be sufficient to cause protrusion of the proboscis". This is untrue; I did not show, or claim to show, what he ascribes to me. The paper to which he refers[2] contains an analysis of the working of the very intricate proboscis mechanism. The first of the three anterior septa is differentiated into several parts and actively assists both the extrusion and the withdrawal of the proboscis, the details varying somewhat with the species; the extent of its responsibility for keeping the resting proboscis in position is unknown. Neither of the other two anterior septa has anything to do with the movements or position of the proboscis.

In the same review Chapman writes that in errant polychætes "the oblique muscles run from a lateral position to a point below the nerve cord" but in *Arenicola* "no oblique muscles are present", that "the lugworm cannot crawl", and that eversion of the proboscis is assisted by "a simple contraction of the posterior end of the lugworm". In fact, of course, the oblique muscles of *Arenicola* are numerous and conspicuous in dissections[3], the worms crawl actively in their burrows, in glass tubes or on the surface of the sand[4], and, as anyone who has watched a vigorously burrowing lugworm will agree, the description of the movements of its hinder part as simple is wide of the mark. He appears to regard the parapodial musculature as largely or entirely derived from the circular muscle layer of the body wall; in fact, as one would expect on functional grounds, the chief parapodial muscles run longitudinally and are derived from the longitudinal layer[5]. It is regrettable that such inexact statements have been put into circulation when accurate information about the movements of lugworms, and the structures which bring them about, was already available.

Striations of Skeletal Muscle

IT seems to have been generally assumed that the structure of myofibrils in skeletal, or striated, muscle is fundamentally similar in all the vertebrate classes, and, in addition, observations on invertebrates, particularly insects, have been widely applied to the muscles of vertebrates. In fact, much of the detailed morphological description of striations of mammalian muscle in histological text-books appears to be based on work on insects, as can be seen by reference to Schafer's well-known text-book[1], or to Cowdry's work on special cytology[2].

This assumption of structural uniformity in all animals is supported by the appearance as seen by using crossed 'Polaroid' glasses, or crossed Nicol prisms, and by staining with Heidenhain's iron hæmatoxylin method.

However, use of a wider range of staining methods, including basic dyes, presents evidence which suggests that species differences in the structure of myofibrils occur, as shown by the differing relation of bands stained to birefringence in different animal types when using the same staining technique. This observation raises the question as to how much of the physiological and biochemical data obtained on other forms is directly applicable to mammalian, and in particular to human, muscle.

Dempsey, Wislocki and Singer[3] (who worked with monkeys, rats and a newt, *Triturus viridescens*) claimed that basic dyes stained the anisotropic (or doubly refractile) segments, and that acidic dyes stained the isotropic (singly refractile) segments. Neither of these statements appears to be of general application. I have previously illustrated[4] the appearances of human muscle as stained by the acidic dye fast green *F.C.F.* On that occasion, relying on the assumption of uniformity and the results of Dempsey, Wislocki and Singer, I misinterpreted the significance of the bands stained by this dye. In man, and other animals so far examined, it is not the isotropic but the anisotropic segments which are stained by acidic dyes.

These observations indicate that in considering the structure of myofibrils more attention should be paid to the possibility of species difference.

Effect of Chloramphenicol on a Fungus

DURING an investigation of the formation of extracellular nitrogen compounds by fungi[1], the effect of chloramphenicol on this process was tested, since in bacteria chloramphenicol is known to interfere with protein synthesis[2] [3] and with the synthesis of enzymes concerned with amino-acid metabolism[4], although it has no effect on the growth of many fungi[5].

A strain of *Scopulariopsis brevicaulis* (Sacc.) Bainier was grown in surface culture in a synthetic glucose–nitrate liquid medium as used previously[1], to which a trace metal supplement containing iron, copper, zinc, manganese and molybdenum was added. Chloramphenicol was added to some of the flasks at a final concentration of 20 or 50 μgm./ml. In the control flasks growth of the fungus was rapid, all the nitrate was assimilated in 6–7 days, and the mean dry weight of mycelium after 20 days was 180 mgm. per flask. The extracellular nitrogen formed represented 16–20 per cent of the nitrogen supplied. In the presence of chloramphenicol, however, growth of fungus was very slow and nitrate did not finally disappear from the medium until 20–40 days after inoculation, when the dry weight of mycelium was

100–120 mgm. per flask. The extracellular nitrogen formed represented 30–35 per cent of the nitrogen supplied. There was no difference in effect between the two levels of chloramphenicol.

This very marked effect of chloramphenicol on the metabolism of *S. brevicaulis* was only found with nitrate as nitrogen source. When nitrate was replaced by ammonia, nitrite, or a mixture of amino-acids, chloramphenicol was without effect and the fungus behaved exactly as in the control flasks. The effect of chloramphenicol in nitrate medium was also completely removed merely by growing the fungus in submerged conditions with vigorous shaking.

The inhibiting effect of chloramphenicol on the fungus in nitrate medium in static culture could not be overcome by the addition of increased trace elements (up to ten times the normal level), or by the addition of yeast extract. It could, however, be overcome by an unknown factor present in commercial glucose and removable therefrom by a cation exchange resin. There was no evidence that the nitrate reductase system was inhibited in the presence of chloramphenicol.

When several other fungi (*Penicillium griseofulvum* Dierckx, *Botrytis allii* Munn., *Aspergillus niger* v. Tieghem, *Fusarium graminearum* Schwabe) were tested in the same conditions as *S. brevicaulis* their rate of growth and nitrate assimilation, and the extent to which they formed extracellular nitrogen compounds, were completely unaffected by chloramphenicol.

No explanation can be given of this effect of chloramphenicol upon *S. brevicaulis* alone among many fungi tested and manifest only in nitrate medium in conditions of surface culture. It seems worth recording if only as an example of that biological specificity which is often so puzzling.

Removal of Osmic Acid Stains

IN the current literature on electron microscopical methods[1] many weaknesses of osmic acid as a fixing agent have been carefully analysed and appropriate safety methods, which would reduce if not entirely eliminate these, have been recommended. No useful advice appears to have been given, however, on the proper cleaning of glass and other utensils after they have become stained with osmic acid or on the removal of osmic acid precipitates, and consequently some wastage of this not inexpensive material at present seems to be accepted as inevitable.

Many years ago, one of us[2], working on an extensive series of peripheral nervous tissue material treated with osmic acid, found bleaching of the sections in 3 per cent hydrogen peroxide extremely useful as a preliminary to the application of other staining methods. Though no special mention was made of this, as it appeared a logical step to take, at that time all glassware and other apparatus contaminated with precipitated osmic acid was washed as a matter of routine with hydrogen peroxide, the strength of the solution depending on the heaviness of the soiling, or the speed required for the finishing of the cleaning process.

With the advent of electron microscopy, osmic acid is again used extensively, and the need for efficient cleaning of glassware and apparatus has reappeared. Hydrogen peroxide was again found fully satisfactory for this purpose and it is used by us as a routine procedure.

It is well known that osmic acid renders cells and tissues difficult to stain by customary methods. Presumably because of this difficulty most workers, in order to achieve the necessary tissue orientation in electron microscopy, use the phase-contrast microscope for this purpose on parallel, thicker sections, though the information thus obtained is not as good as that provided by stained preparations.

At present we are studying systematically the staining properties of sections fixed with osmic acid and embedded in methacrylate after bleaching them in hydrogen peroxide. It is already apparent that most staining methods are applicable to these sections with reasonable success and without any major modification in the procedure.

Details of this work will be published elsewhere.

An Apparently Simple Case of Population Control

IT is not usually possible to discover what factors control any particular population, that is, what factors act more strongly against the population as it increases and so tend to keep its numbers constant. In a small planted beech wood just west of Marlborough (Nat. Grid Ref. *SU* 175680) there is a population of the common snail *Helix aspersa* which seems to be controlled in a very simple manner. The trees have small buttresses at their bases, leaving narrow caves between, and in the winter the snails crawl into the caves to hibernate. When I visited the wood on January 21, 1954, with Drs. S. M. McGee Russell and P. M. Sheppard, we found no *aspersa* were hibernating near the outsides of the caves: all were deeply inside. When Dr. Sheppard visited the copse in the previous autumn there were many snails not fully in the crevices, and he tells me that there were far fewer predated shells then than we saw in January. It was as if all snails which were hibernating in a position in which a predator could reach them had been eaten, while those in inaccessible positions survived. As these inaccessible positions would not change greatly from year to year, this system would keep the population at a constant size in the same way that an overflow pipe keeps water in a tank at constant depth. Squirrels were probably the predator concerned.

This colony is unusual not only in its system of control. The snails were more markedly banded than garden snails, and most were immature. By using sticks we managed to secure 134 live snails of which only 30 were adult.

Friday, October 24

British Psychological Society, Occupational Psychology Section (in the Department of Psychology, Birkbeck College, Malet Street, London, W.C.1), at 1 p.m.—Mrs. M. Bucklow: "Psychological Work in the Commonwealth Bank of Australia".

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 4 p.m.—Symposium on "Engine Noise and Noise Suppression".

University of London (at Senate House, London, W.C.1), at 5.30 p.m.—Prof. Paul Veyret (Grenoble): "Modern Theories of the Structure of the Alps".* (First of three special university lectures. Further lectures on October 27 and 29.)

Society of Dyers and Colourists, London Section (at the Waldorf Hotel, Aldwych, London, W.C.2), at 7 p.m.—Mr. A. Lucas: "Colour in Art" (Sixth London Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Sir Lawrence Bragg, F.R.S.: "Treasures in the Collections of Apparatus at the Royal Institution".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (registered pharmaceutical chemist, graduate in pharmacy or science, and preferably with research experience) in Pharmaceutical Chemistry in the Department of Pharmacy and Biology—The Registrar, College of Technology, Birmingham 4, quoting "C" (October 23).

Senior Lecturer (with a degree in electrical engineering and Corporate Member of the Institution of Electrical Engineers) in the Department of Electrical Engineering—The Registrar, Hatfield Technical College, Hatfield, Herts (October 27).

Assistant (science graduate, preferably with qualifications in physiology or biochemistry, or both) in Clinical Chemistry—The Secretary, The University, Aberdeen (October 31).

National Coal Board Postdoctoral Fellow in Physical Chemistry, for research work in connexion with the study of solids by a number of techniques such as mass spectroscopy—The Registrar, The University, Edgbaston, Birmingham 15 (October 31).

Temporary Lecturer (qualified in applied mathematics) in Mathematics—The Registrar, University College of North Staffordshire, Keele (October 31).

Research Assistant, for work on the structure of crystalline proteins using X-rays and electronic computers—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (November 1).

Meteorological Officers (with either (*a*) a first- or second-class honours degree (or equivalent) in physics or mathematical physics or mathematics or engineering or (*b*) a degree (or equivalent) in meteorology) in the Irish Meteorological Service—The Secretary, Civil Service Commission, 45 Upper O'Connell Street, Dublin, Ireland (November 6).

Experimental Officer-Horticulturist (with a university degree in agricultural science or equivalent training in horticulture, and also practice on a large commercial or Government establishment, university or other research station) at the Irrigation Research Station, C.S.I.R.O., Griffith, N.S.W., Australia, for work in connexion with the layout of crop experiments on fruit, pastures and vegetables and for detailed work on plants under close environmental control—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting appointment No. 500/100 (November 8).

Chair of Geography in the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (November 15).

Lecturer (preferably with postgraduate experience in biochemistry) in Animal Nutrition in the Department of Animal Husbandry and Veterinary Hygiene, to undertake teaching and research—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (November 15).

Senior Lecturer or Lecturer in Mathematics at Canberra University College, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 15).

Lecturer or Assistant Lecturer in Physical or Inorganic Chemistry at Makerere College (University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 25).

Chance Chair of Mechanical Engineering—The Registrar, The University, Birmingham 15 (November 30).

Lecturer in Physics at the University of Tasmania, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 30).

Lecturer or Assistant Lecturer in Zoology at the University of Malaya—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 30).

Lecturer in Aeronautical Engineering—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Lecturer in Physics—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Lecturer (with a degree in chemical engineering or metallurgy, some industrial or research experience, and the ability to teach the engineering aspects of extraction metallurgy, including fluid mechanics and heat transfer) in the Metallurgy Department—Prof. F. D. Richardson, Metallurgy Department, Imperial College of Science and Technology, London, S.W.7.

Medical Laboratory Technician (qualified male or female) in the National Blood Transfusion Service—The Administrative Officer, Regional Blood Transfusion Centre, Crescent Drive, Brentwood.

Physics Master, to take the subject to scholarship level—The Headmaster, St. Albans School, Abbey Gateway, St. Albans.

Research Assistant in the Pathology Department, for work involving the application of X-ray methods to the study of bone structure—The Secretary, Pathology Department, Institute of Orthopædics, 234 Great Portland Street, London, W.1.

RESEARCH ASSISTANT (with a mechanical engineering or physics degree with a strong mathematical ability), to carry out theoretical and experimental work in a plastic-elastic body—The Clerk to the Governors, Woolwich Polytechnic, London, S.E.18.

SENIOR CLINICAL PSYCHOLOGIST, to organize and maintain a full psychological service for the hospital and its associated out-patients clinics—The Group Secretary, Cherry Knowle Hospital, Ryhope, near Sunderland.

ZOOLOGIST (graduate in zoology of a British university) at the Dove Marine Laboratory—The Registrar, King's College, Newcastle-upon-Tyne.

Photography at work

helping to ensure the purity of metals

Constant checks on the purity of all metal supplies delivered to the Aluminium Wire & Cable Company help to ensure that the finished products will meet the most exacting electrical and mechanical requirements. These checks are made rapidly and accurately by spectrographic analysis. The Company writes:

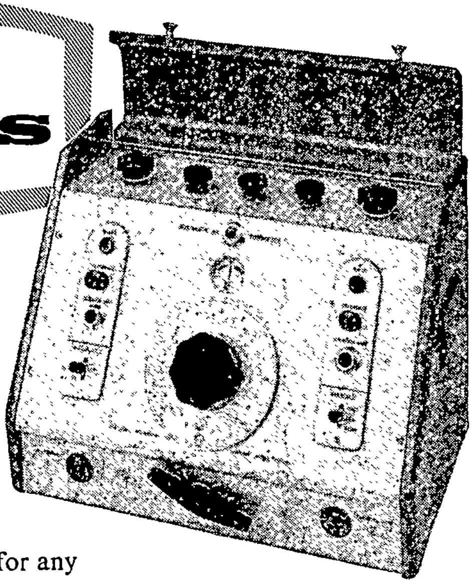
"For the high degree of accuracy required in the micro-photometric determinations of trace elements, it is essential that the photographic plates used should be uniformly coated with a fine-grade emulsion having a 'straight-line' characteristic curve and providing a high contrast, especially in the ultra-violet region of the spectrum.

"We use Kodak B.10 rapid-processing spectrographic plates exclusively for this work."

B.10 Kodak High-Contrast Rapid-Processing Plate

Kodak Limited, Industrial Sales Division, Kodak House, Kingsway, London, W.C.2.

AUTOMATIC TITRATIONS



ARE easily carried out by the E.I.L. Automatic Titrimeter, Model 24. This instrument is fully automatic, switching itself off on reaching the pre-set end point.

Either the volumetric or the coulometric method may be used, and separate titration units for each type are available. Duplicated connections are provided on the Control unit.

The endpoint setting dial is calibrated in pH and in millivolts, and the equipment can be used for any type of chemical reaction producing a determinate change of e.m.f. The accuracy of titration is 0.05 c.c. in 50 c.c.

SCIENTIFIC AND INDUSTRIAL RESEARCH IN GOVERNMENT DEPARTMENTS

IN its fifth report for the Session 1957–58* the Select Committee on Estimates considers the work of the Department of Scientific and Industrial Research. It is, however, limited to the work carried out directly by the Department through its fourteen experimental establishments: no comment is offered on the Department's work in relation to the universities, although this was considered in evidence submitted to the Committee. Moreover, apart from the single recommendation that the admissible reasons for refusing applications for membership of a research association should be explicitly stated in the terms of grant, and that the councils of the research associations should be required to furnish a list annually of the applications which they have rejected, with reasons, the work of the research associations is likewise only noted in evidence. Indeed, the Select Committee professes itself to be satisfied, in general, with the working of the research association scheme. Its report therefore deals solely with the organization and administration of the Department from the point of view of the Council's expenditure of the appropriate vote, and is thus in fact concerned with the sum of £5,775,587 gross expended on the fourteen experimental establishments out of the Department's gross estimate for 1958–59 of £10,472,993, though its criticisms and comments inevitably include also the headquarters expenditure of £537,206.

It will be seen from the foregoing alone that the Select Committee does not attempt to assess the place of the Department in Britain's general organization for research and development. The lacuna left two years and more ago by the Jephcott Committee remains unfilled, and although the Select Committee on Estimates makes a number of sensible suggestions, these might have been expected to have come from the Advisory Council on Scientific Policy. Such reference to the Advisory Council as is made in this report, which touches so closely on the responsibilities of both the Advisory Council and the Lord President of the Council, seems to endorse Sir Hugh Beaver's strong criticisms early this year. Furthermore, it is surprising that the work of the Department should have been submitted to a searching examination so soon after the report of the Jephcott Committee and the subsequent re-organization of the Department.

It is not that the Department comes badly out of this review. On the contrary, the Select Committee on Estimates recognizes that the new Executive Council of the Department is already engaged in a full-scale review of the work of all its establishments and has begun to re-shape and re-formulate policy. Indeed, it admits that many criticisms which might have been levelled against the Department's general organization as lately as November 1957, when the present inquiry began, had been rendered out of date by July 1958. Specifically it wholeheartedly welcomes the initiative of the Council in undertaking its present review and in establishing a policy of continuous reviews as likely to facilitate proper timing in terminating a piece of research—an operation as important as timing its institution and possibly more difficult as well as less frequently practised.

Apart from this general comment, the Estimates Committee's remarks relate to the relations of the Department with other government departments and with industry, and it is the other departments that incur the gravamen of its criticism. Four of the Department's experimental establishments differ from the other ten in that they work mainly for one particular government department, and of these four, the Road Research Laboratory was studied in some detail. Apart from its work for the Colonial Office, the Laboratory's work is principally on behalf of the Ministry of Transport and Civil Aviation, and although the Committee was satisfied with the liaison between the two departments, it comments trenchantly that contracts for road construction are only very exceptionally shown to the Laboratory. Without seeing the actual prices quoted, the Committee points out, the Laboratory's experts can scarcely be satisfied that the new practices they have recommended are properly understood and any financial savings made possible by these practices are in fact being achieved, nor can the Laboratory be sure that their recommendations are used unless regular reports are made to them about costs of construction and subsequent performance. Accordingly, the Committee recommends that, quite apart from other considerations, the tenders received by the Ministry of Transport and Civil Aviation from contractors for work to be done to new specifications should be shown to the Laboratory as a matter of routine, and that steps should be taken to inform the Laboratory of the performance in practice of construction in accordance with new specifications.

Nevertheless, however perfect the liaison between two departments, the Select Committee believes that, where practicable, amalgamation of two related departments is preferable. On the evidence it received, the Committee leans strongly to the view that the Road Research Laboratory would better be placed under the Ministry of Transport and Civil Aviation. This would ensure that the Ministry was aware in advance of what staff and facilities are available and reduce the risk of drawing up research schemes which cannot be undertaken. It should also facilitate the dissemination of the results of the research where they are most likely to be used to advantage. The Ministry, it believes, is in a better position to do this than the Department of Scientific and Industrial Research, just as it could better judge priorities in work affecting its own department; fundamental research at present carried out by the Laboratory could equally well be carried out by the Building Research Station. The Committee quite rightly notes that such fundamental work is likely to apply to a wider field than that of road construction, but it seems to have overlooked the value of fundamental and applied research proceeding side by side in the one laboratory, from the point of view of attracting and retaining staff and of stimulating new ideas. In regard to the former, it was stated in the evidence that the scientific and experimental staff is at present some 7·5 per cent below strength, and that younger men are attracted to places where the research programmes are most interesting.

---

* Fifth Report from the Select Committee on Estimates together with part of the Minutes of the Evidence taken before Sub-Committee B and Appendices, Session 1957–58—The Department of Scientific and Industrial Research. Pp. xvi+165. (London: H.M. Stationery Office, 1958.) 9s. net.

The Select Committee, however, is content here with the general recommendation that the Government should specifically consider the question which Department should control the Pest Infestation Laboratory, the Radio Research Station, the Road Research Laboratory and the Water Pollution Research Laboratory. The recommendation is clearly in line with the trend of policy which the new Council has already indicated in its first annual report; but it also suggests that the whole question of the organization of the national research effort is being re-opened and requires consideration from very much wider angles than those of a department. That is also implied in the recommendations relating to co-operation between the Admiralty and the Department of Scientific and Industrial Research; though here, as in its fifth report for the session 1956–57, the Committee is critical of the Admiralty rather than the Department.

The Select Committee accepts the Admiralty's view that problems of ship design and propeller design (see also *Nature*, October 11, p. 988) may differ considerably for warships and merchant ships; but it believes that much greater efforts are required to promote consultation and liaison between the scientists concerned, in order to avoid unnecessary duplication of effort and uneconomic use of facilities, quite apart from the question of availability of knowledge. While the Committee is satisfied that Admiralty knowledge and opinion are fully available to the Department at the most important stage for avoiding overlapping—when the Department's research programme is drafted—the complementary process does not occur, nor are the provisions for making available to the Department the knowledge in the Admiralty's possession satisfactory. The Department of Scientific and Industrial Research has no *ex officio* members of any committee in the Admiralty which plans research, and no opportunity of commenting on the programme which the Admiralty proposes to carry out in their tank at Haslar. Further, no real attempt is made to co-ordinate the use of available facilities for research on ship and propeller design.

Accordingly, the Estimates Committee refuses to accept the view that considerations of secrecy should preclude senior officers of the Department of Scientific and Industrial Research from knowledge of the Admiralty's research plans and makes the following recommendations. First, that the Admiralty should in future afford some officers of the Department an opportunity of commenting on the Admiralty's programme of ship and propeller research at the earliest possible stage, and certainly before the programme is finally settled. Secondly, the Admiralty and the Department should work out a scheme for the regular use of all the available facilities for research in this field by both departments. Thirdly, selected officers of the Department of Scientific and Industrial Research should be given free access to all the scientific information relating to ship and propeller design at present in possession of the Admiralty which the Admiralty would be prepared to disclose if it were specifically requested.

These are sensible recommendations, which, quite apart from their value in checking undesirable secrecy, are in harmony with those which the Select Committee made in the previous session. They point, moreover, to the importance of much closer co-operation between the Defence Research Policy Committee and the Advisory Council for Scientific Policy. If that liaison were in fact satisfactory, it is difficult to see how such recommendations as these could have been left to the Select Committee on Estimates.

BOOKS ON EVOLUTION

Evolution by Natural Selection

By Charles Darwin and Alfred Russel Wallace. Pp. viii+288. (London: Cambridge University Press, 1958. Published for the XV International Congress of Zoology and the Linnean Society of London.) 25*s*. net.

Darwin's Century

Evolution and the Men Who Discovered It. By Prof. Loren Eiseley. Pp. xvii+378. (New York: Doubleday and Company, Inc., 1958.) 5 dollars.

A Century of Darwin

Edited by S. A. Barnett. Pp. xvi+376+5 plates. (London: William Heinemann, Ltd., 1958.) 30*s*. net.

Embryos and Ancestors

By Sir Gavin de Beer. Third edition. Pp. xii+197. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 25*s*. net.

THESE books are some of the many published during the past year in response to the renewed interest in Darwin and his work stirred up by the centenary of the meeting of the Linnean Society in 1858 at which he and Wallace first published the theory of natural selection.

The first book contains reprints of Darwin's essays of 1842 and 1844, which he did not publish, and of the papers given to the Linnean Society. It is prefaced by a short discussion of the present position by Sir Gavin de Beer and by an introduction written by Sir Francis Darwin for the essays when they were published in 1909.

It is useful to have these classical writings in an easily accessible form. They are important for the history of Darwin's thought and especially in showing how clearly he was able to outline his theory in 1842 after no more than five years work. The main part of his paper of 1858 was indeed an almost entirely unchanged extract from the essay of 1844. His views had been scarcely at all altered in the interval. This also appears from the many notes that are given correlating what is said in the essay with parallel passages in "The Origin".

The second book is a history of the development of belief in the fact of evolution and its theory in the nineteenth century. When he comes to write of early genetics, the author extends his account to the first few years of the present century, but he does not go further ; we are told to expect a second volume carrying the story to the present day. The book is a scholarly and well-documented account of the subjects it deals with, but there are some omissions that seem surprising. The reactions in the world outside science are scarcely at all discussed. Perhaps, the author felt that his subject lay in the history of biology and that he should not concern himself with what happened elsewhere. But the interactions were undoubtedly mutual, and a full discussion of the course of events in biology requires some consideration of the development of thought in general.

Less easily understood are two other omissions. The author says very little of the transcendental theories of the early part of the nineteenth century. Darwin may not have been greatly influenced by the work of this type, for it was not his kind of zoology, but it was dominant in the years before he wrote "The Origin" and its theories certainly influenced the reactions of many zoologists to the new theory, especially in Germany (von Baer, Kölliker). Again, anyone reading the book without some previous knowledge would get the impression that the opposition of the early geneticists at the beginning of this century to the theory of evolution by natural selection was shared universally by the biologists of the time. The views of the many who denied the force of the Mendelian evidence against the theory—on the basis of their experience of animals and plants in Nature, of the nature of evolutionary change as seen in palæontological series of strata, and of results such as those of Galton on heredity in man—are not discussed.

All the same, the chapters of the book regarded as accounts of some aspects of the history are valuable, especially, perhaps, those on Darwin's reactions to the claims of the physicists to deny a longer history of the world than a few million years, and on his disagreement with Wallace over the evolution of man. The book should be read, and the appearance of a second volume will be awaited with interest.

The third book contains fifteen short articles by various authors, many of them eminent, on the present position in fields of the study of evolution with which they have been particularly concerned. Most of the contributions are valuable as being clear and concise summaries, but none of the authors has space to do more than this. In fact, the book as a whole suffers from the usual limitations of composite books of this kind. The articles will be useful to anyone who has a sound background of modern views of evolutionary theory, but it is less likely to be useful to those who lack this background of knowledge ; no general view of the present position will be gained. It is not possible to discuss the separate articles in a short review such as this. One contribution, that of D. Michie, on "The Third Stage of Genetics" seems scarcely in place in a volume intended to review "the present status of Darwinian ideas in biology". In it views are expressed which would be unlikely to be endorsed by the majority of geneticists, at least in Britain and America.

The last of these books is less closely concerned with the centenary of the theory of natural selection. It is a revision of Sir Gavin de Beer's well-known book, first published in 1930. The argument is unaltered from earlier editions, but it is expanded with further examples in many places and with three additional chapters on embryology and taxonomy, embryology and homology, and the germ layers. The book is, throughout, concerned with re-interpretation of classical phylogenetic concepts in the light of modern knowledge and in particular with disproof of Haeckel's theory of recapitulation—more a flogging of a dead horse now than it was in 1930, largely owing to the earlier editions of this book—and of the cruder forms of the germ-layer theory. de Beer attributes much importance in evolution to the various types of neoteny, perhaps more than some zoologists would allow. It is good to have this restatement of his views. G. S. Carter

MODERN MICROSCOPY

X-ray Microscopy and Microradiography

Proceedings of a Symposium held at the Cavendish Laboratory, Cambridge, 1956. Pp. xviii+645. (New York: Academic Press, Inc. ; London: Academic Books, Ltd., 1957.) 16.50 dollars.

During the post-war years, one of the major developments in the technique of scientific inquiry has been the spectacular development of microscopy. While electron microscopy undoubtedly scores on the grounds of the high resolution already achieved, the great penetration of X-rays in matter offers great promise in the extension of microscopy to X-ray wave-lengths. The present volume presents the full text of the papers delivered at the first symposium on X-ray microscopy and X-ray micrography together with short extracts of the discussions. All the current techniques of X-ray microscopy – contact X-ray microradiography, reflexion X-ray microscopy and point projection X-ray microscopy – are fully dealt with each by a number of authors distinguished in this field.

The first section deals with the basic principles of these three methods and points out the conditions under which each method finds its greatest application. The following three and several later chapters, referring as they do to the construction of the necessary apparatus including X-ray tubes, will be of greater interest to the experimental physicist than to the prospective user, but nevertheless form a coherent and instructive series. In other chapters methods and techniques are dealt with fully and some applications in biological, medical and metallurgical fields are described.

The total effect left on reading this book is that here is a technique which has not yet reached full bloom but is advancing rapidly. Both contact X-ray microradiography and point projection X-ray microscopy already yield images with resolution at least as good as that in light microscopy, and indications are given that the resolution in the former (also the easier) method is even now so high that attempts are being made to enable the magnification of the original contact image to be achieved in an electron microscope in place of a light microscope. The discussion of reflexion X-ray microscopy is, however, on the whole discouraging.

The papers are somewhat uneven in quality, as might be expected in the unabridged presentation of articles by a large number of authors but, on the whole, the book reads remarkably smoothly and the editors are to be complimented on a compilation which welds the diverse contributions into a coherent whole. The book well repays close study by all workers, particularly biologists, interested in future developments in microscopy.

R. D. Preston

MODERN CYTOLOGY

International Review of Cytology, Vol. 6

Edited by G. H. Bourne and Prof. J. F. Danielli. Pp. x+566. (New York: Academic Press, Inc.; London: Academic Books, Ltd., 1957.) 12 dollars.

THIS volume contains twelve essays in various fields of cytology, the whole forming a very valuable contribution to knowledge. In some cases the subjects dealt with have advanced so rapidly since the manuscripts were received that their authors could have wished to have been able to add to their conclusions. The antigens of *Paramecia* were first studied so far back as 1905 by Rössle, who showed that rabbits immunized against these Protozoa developed antibodies capable of paralysing them. Sonneborn's discovery of the mating type system of *Paramecium aurelia* made possible further work on cellular processes in general. G. H. Beale of the Department of Animal Genetics, Edinburgh, now discusses the antigen system of *Paramecium.* Beale believes that the hypothesis of autonomous cytoplasmic states, and the hypothesis of variable gene activity, contain possible explanations of most, but not of all, of the known facts.

Sajiro Makino of Hokkaido University, Japan, writes about those remarkable ascites tumours of rats, which can be transferred from animal to animal by injecting a small amount of tumour ascites into the peritoneal cavity with a sharp pipette. Makino's work shows that the most frequently occurring tumour cells possess characteristic chromosome number modes, along with particular patterns, and form a stem-cell lineage, the members of which serve as the primary progenitors. Makino mentions tumours with distinct chromosome numbers—39, 66, 84, 91, etc.—which is a remarkable contribution to the study of cancer.

Arthur W. Pollister and Priscilla F. Pollister write on the structure of the Golgi apparatus. They state that Jan Hirschler originated the idea that the parts of the Golgi apparatus are formed of a thin lamella, or membrane. While we are all for bringing the work of Hirschler before the eyes of the impatient young men who have an electron microscope, we certainly do not consider that Hirschler knew that what he believed to be the lamelliform Golgi membrane was made up of a pile of separate lamellae or saccules usually of fairly definite number. That the blackened "nebenkern batonette" of molluscs is some kind of a multiple structure was first pointed out by Beams *et al.* What also seems important is that Hirschler in 1932, in the *Comptes rendus de la Société de biologie* (109, 1157), first described the *granulated* ergastoplasm in the spermatid of *Macrothylacia rubi.* Hirschler used material fixed in modified Hermann's fluid, then post-osmicated.

From Palermo comes an interesting article by A. Monroy on the fertilization and activation of the egg, and from Berkeley, California, by Robley Williams, a very full review in the role of the electron microscope in virus research. He writes, "We may hope for techniques that will allow us to put our finger on an image of a tiny particle, and say with some confidence that—this is a *virus* particle".

Arthur J. Hale of the University of Glasgow has sixty pages in the histochemistry of polysaccharides. Those who wish to read an authoritative discussion, for example, on the relationship between metachromasia, periodic acid–Schiff staining and polymerization, will find it here. J. Gross of the State University of New York has attempted to relate follicular structure of the thyroid gland to colloid turnover and iodine metabolism. He correlates our knowledge of the nature and function of the parafollicular cells.

Elio Borghese of the University of Cagliari, Italy, has provided a most useful article on the application of histochemical methods to embryonic tissues. One of the most remarkable contributions in this field was the discovery by Chiguoine in 1953 that the primordial genital cells could be recognized in the mouse embryo on the eighth day of gestation by their high alkaline phosphatase rate. This article is recommended for senior students of the comparative physiology of reproduction. R. J. O'Connor of the Westminster Medical School, London, has a speculative review of the information available about the metabolism of the early embryos of the amphibians, the chick, and the sea-urchin. His contribution can be read in conjunction with that of Borghese.

G. Siebert and R. M. S. Smellie of Johannes Gutenberg University, Mainz, and the University of Glasgow, respectively, have contributed an account of the biochemistry of isolated cell nuclei. Conveniently, the next essay by George H. Hogeboom, Edward L. Kuff and Walter C. Schneider is on the cytochemistry of tissue homogenates. These articles are on subjects which are advancing swiftly. George H. Hogeboom died on July 6, 1956, a great loss to his colleagues at Bethesda, and to this difficult and promising field of modern cytology.

The final article by Freda Bowyer of King's College, London, on the kinetics of the penetration of non-electrolytes into the mammalian erythrocyte, is an abstruse and masterly treatment of the problem of red cell transfer. At present no one has devised a decisive experiment which would eliminate any of the three postulated mechanisms—carrier, enzyme, or pore.

J. Brontë Gatenby

AN APPROACH TO ORGANIC CHEMISTRY

A Modern Approach to Organic Chemistry

By Prof. J. Packer and J. Vaughan. Pp. x+973. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 84*s.* net.

THE teaching of a progressive science has been likened to "The Hunting of the Snark" in that the objective is indefinite, changing with time as major research achievements have to be incorporated within limited curricula, and dependent more on the enthusiasm than on the erudition of the teacher. However, a comprehensive text-book should provide a balanced guide to both teachers and students, approaching the advancing front of the subject by the clearest possible route, avoiding laborious minutae of the past and showing circumspection in treatment of theories. In producing a new major text-book of organic chemistry the joint authors, from the University of Canterbury, New Zealand, deserve commendation both for the extent of their labours and for their general plan in attempting to teach essential facts through the clear presentation of electronic theories of molecular structure and reaction mechanisms.

The book is decidedly British in its educational outlook, rather than American or Swiss. The modern approach avoids the usual alternatives either of detailing nineteenth-century structural theories or of crowding an indigestible mass of facts into the opening chapters, and clearly presents in its first 150 pages most essential features of modern structural theories together with the homolytic and heterolytic mechanisms of reaction processes. It achieves this in chapters dealing, by title, with hydrocarbons, their halogen derivatives, and amines. Thereafter the volume deals with other functional groups in the conventional order, placing aromatic chemistry after 500 pages of aliphatic chemistry and ending with but 45 pages of heterocyclic chemistry. Proteins, terpenes, steroids, purines, alkaloids and natural colouring matters do not receive treatment, so that the lengthy volume is suited only to a limited curriculum.

The worst failing of old-fashioned text-books is repeated in that optical isomerization is not introduced until hydroxy-acids are dealt with among bifunctional molecules (p. 371). Walden inversion then gets brief mention (p. 390), though the S_N2 mechanism is described much earlier (p. 114). Consequently, one cannot find in the whole volume the important modern concept of the stereospecificity of bimolecular reaction processes, or even mention of *trans* addition and elimination reactions. Modern ideas of steric hindrance and molecular conformation are clearly beyond the scope of the book: structures for *cyclo*-hexane are correctly given on p. 41, though the interconversion of 'boat' and 'chair' forms is said to be tautomeric. Even later, in connexion with acetoacetic ester, no clear evidence is cited as to why tautomerism is believed to be an acid-base catalysed process, though the diagrams representing reaction mechanisms are correct.

The readable form and the typography of the volume have the invariable high standard of publications of the Clarendon Press, but the chapters on aromatic chemistry contain even more plain hexagons for benzene than Kekulé structures. The two symbolisms are found together even on the same page. It is fortunate, therefore, that the book does not include modern work on alicyclic compounds, since it is now conventional to restrict the use of the plain hexagon to denote the *cyclo*-hexane ring.

Yet, though the omissions from this book of several salient topics of importance cannot be overlooked, the volume does present in a clear, interesting fashion a very large bulk of important factual matter with which chemistry undergraduates need to become conversant. The authors have, in fact, taken a conventional text-book and have added to it, *seriatim*, electronic formulæ for the mechanism of each reaction described. They do this by following meticulously the authoritative guides provided by the monographs of Sidgwick and Ingold. By retaining tables of physical properties they endeavour to maintain comprehensive coverage for a degree course and hence bulk the pagination.

Thus in this essay at a modern text-book of organic chemistry the Bellmen have started on a true course, but their leadership has failed in mid-ocean. Firm handling, with judicious pruning and a wider objective, is needed to make this a text that will command wide respect. W. A. Waters

MICROSAUR RELATIONSHIPS

Revision of the Gymnarthridæ American Permian Microsaurs

By Joseph T. Gregory, Frank E. Peabody, and Llewellyn I. Price. (Peabody Museum of Natural History, Yale University, Bulletin 10.) Pp. x+77. (New Haven: Peabody Museum of Natural History, Yale University, 1956.) n.p.

The Microsaurs are not 'little reptiles' as their name implies but are a group of ancient amphibians that must have arisen in Devonian times, that was certainly abundant in the Carboniferous, and had a few Permian survivors, of which the Gymnarthridae are especially interesting. In general, Microsaurs are not nearly related to the Labyrinthodonts and differ from them in the absence of an otic notch in the skull and in the resulting simplicity of the supratemporal region. They are Lepospondyls and have the notochord invested by bony cylinders.

The Gymnarthridae themselves are an aberrant group that has long been ill defined. Cope described *Pariotichus brachyops* in 1878 from an imperfect skull from the Lower Permian of Texas. E. C. Case described *Gymnarthrus* in 1910 and there has been continued confusion in the identity of this genus itself and in its relationships. *Gymnarthrus* was first thought to be a reptile, then a Stegocephalian, and much of the additional materials collected and studied have contained elements of Captorhinid Cotylosaurs.

Although Case himself did much in later years to help clear up the confusion, the poor state of preservation of much of the material and the small size of the specimens, for Microsaurs are usually but a few inches long, have made elucidation of their relationships difficult.

Within recent years much better material has been obtained from the Permian fissure deposits in quarries near Fort Sill in Oklahoma, and several workers had independently begun revision based on their respective collections. In this volume much of this research has been co-ordinated. The original type specimen of *Pariotichus brachyops* Cope is redescribed and refigured and recognized as a Microsaur, but most of the species referred to this or to supposedly related genera can now be identified as Captorhinomorph reptiles.

The type-specimen of *Gymnarthrus willoughbyi* Case is here regarded as a synonym of *Cardiocephalus sternbergi* Broili, and *Euryodus*, *Goniocara*, *Pantylus* and *Ostodolepis* prove to be related genera, although it is not quite clear at this stage that *Pantylus* and *Ostodolepis* really belong to the family for which the name Gymnarthridae is retained.

These Microsaurs are all small-skulled with short pre-orbital, and long post-orbital, regions. Only *Cardiocephalus* has a parietal foramen. All the above genera, except *Pantylus*, come from the Arroyo formation of the Clear Fork group of the Lower Permian. *Pantylus* has been found in the Clyde and the Putnam formations of the slightly older Wichita group.

Separate sections of the book deal with the auditory region of the Microsaurs and its phylogenetic significance; with Gymnarthrid tooth implantation and succession; and with the postcranial elements.

The authors' conclusions are that the Microsaurs are probably ancestral to the Gymnophionans and are much less closely related to the Nectridia and the Urodela derived from them. The Aistopoda are still more remotely connected. W. E. SWINTON

THE IONOSPHERE

The Ionosphere

Its Significance for Geophysics and Radio Communications. By Dr. Karl Rawer. Translated from the German by Ludwig Katz. Pp. 202+10 plates. (London: Crosby Lockwood and Son, Ltd., 1958.) 42*s*. net.

QUITE apart from its vital role as a propagating medium for the radio waves used in long-distance communication, the ionosphere forms an extremely important and fruitful field for geophysical investigation, and, moreover, one in which there is pressing need for further work to be done—work which embraces several branches of physical science. It is surprising, therefore, considering that the world's communication services are largely established by its means, how little attention is yet given to the ionosphere by the average radio engineer.

To the geophysicist as well as to the radio engineer, therefore, the publication of an English translation of Dr. Rawer's original German book on the ionosphere should be welcome, for though there is a vast scientific literature on the subject, there are very few textbooks upon it.

The author first deals with methods by which the ionosphere is 'sounded', including those of radio reflexion, spectroscopic and geomagnetic observation and with a brief mention of the possibilities of rocket flights. The results obtained by these operations are then dealt with in considerable detail, after which the theory of layer formation is discussed, including that of atmospheric ionization by various solar radiations and that of de-ionization by different processes. Chapter 4 discusses the regular changes to which each layer is subject and also describes the different kinds of ionospheric disturbances and other irregular phenomena. An interesting explanation of the special conditions which prevail within the polar circles is given. The final chapter is devoted to the influence of the ionosphere on radio-wave propagation and to methods for predicting the radio conditions in terms of the usable frequency bands. British, Australian and American methods for doing this are described, but the author devotes most space to the method developed by his colleagues and himself, and which is considerably more complicated than the others. Little information is, however, given as to the accuracy of prediction achieved by any of the methods, and one judges, from the final section, that there is room for improvement in this direction.

The book is of a suitable length for a comprehensive introduction to the subject, though much of the material is very condensed. The translated English is not always good, and this, together with the condensed style, tends to render the reasoning, in parts, a little obscure, which may make the book hard going for the student. Against this, however, is the fact that it is profusely illustrated by line drawings and plates, and frequent samples of data in tabular form are presented. An extensive bibliography is given at the end. Undoubtedly, therefore, the book will serve, for many, as a useful introduction to the ionosphere.

T. W. BENNINGTON

BREWING

A Textbook of Brewing

Vol. 2. By Prof. Jean De Clerck. Translated by Kathleen Barton-Wright. Pp. xx+650. (London: Chapman and Hall, Ltd., 1958.) 105*s*. net.

WHEREAS Vol. 1 was predominantly descriptive in the sense of being concerned with various processes as actually managed in maltings and breweries, the present volume is largely complementary in consisting of an account of corresponding laboratory analytical procedures.

This account of practice in a brewing laboratory covers an extraordinarily wide range and there will be few to whom all the numerous estimations are familiar. For example, in addition to dealing exhaustively with the raw materials of brewing and with worts and beers as commonly understood in Britain, the book includes methods relating to vitamin assays, several antiseptics, synthetic sweetening agents and artificial colouring matters which would not normally come into question in Britain. A further valuable feature is a substantial section dealing with the specification of diverse accessory materials such as filtering agents, pitch, detergents, finings, plastics, varnishes, and various fuels and lubricants. Not least important is the concluding part amounting to about 70 pages, which describes the application of such methods to scientific, including microbiological, control in breweries and maltings. The descriptions of the methods themselves are, of course, factually based on published data as indicated by adequate references, while the applications are more in the nature of informal recommendations, subject to modification according to the circumstances prevailing in individual establishments.

This book is clearly not intended primarily to establish any scientific principles. For example, to take a single example at random, various empirical estimations of the tannins in hops are adequately described, but the reader must seek elsewhere for evidence that the different results can be interrelated or that they refer to recognizable chemical entities. Other topics, such as the determination of the resistance of beers towards the development of haze, are almost matters of controversy. On the other hand, much of the detail, for example, the colours of light of various wave-lengths (p. 25), and many of the illustrations might seem somewhat tedious or even unnecessary to those whose knowledge is such that they might be turning to this encyclopædic volume. Despite these reflexions, however, this book is the most up-to-date and possibly the most comprehensive handbook and reference work of its kind in existence. Its great virtue lies in describing diverse methods in such detail that, thanks in large measure to the excellence of the translation and general presentation, non-specialists can hope to achieve useful results. Within these limitations it is likely to prove invaluable to those engaged in laboratory work in connexion with brewing. A. H. COOK

Tables of Light-Scattering Functions

Relative Indices of Less than Unity, and Infinity. By R. H. Boll, J. A. Leacock, G. C. Clark and S. W. Churchill. Pp. viii + 360. (Ann Arbor, Michigan: University of Michigan Press, 1958. Published for the Engineering Research Institute.) 9·50 dollars; 71*s.* 6*d.*

Tables of Angular Distribution Coefficients for Light-Scattering by Spheres

By Chiao-Min Chu, George C. Clark, and Stuart W. Churchill. Pp. xv + 58. (Ann Arbor, Michigan: University of Michigan Press, 1957.) 3 dollars.

THE scattering of light by small particles is of interest in several fields, for example, aerosol physics, atmospheric physics, astronomy, and colloidal chemistry. The fundamental theory rests on Mie's solution of the Maxwell equations for the interaction of a linearly polarized wave and a single spherical particle of diameter D comparable with or larger than the wave-length λ. The solutions are in the form of infinite series of complex mathematical functions, tabulated values of which are still not available for many important conditions.

In the first of these two volumes, values of the scattering coefficient K and the amplitude functions are tabulated for values of the particle refractive index in the range 0·6–0·93, and also infinity, and for 39 values of $\alpha = \pi D/\lambda$ in the range 1–200. These functions are particularly applicable to bubbles of a gas in a liquid or a solid and to the dispersion of a liquid in another of higher refractive index.

In the second publication are tabulated the scattering coefficients and the coefficients of angular distribution of randomly polarized radiation scattered by a sphere for 9 values of refractive index m ranging from 0·9 to 2·0, and also for $m = \infty$, and for values of $\alpha = \pi D/\lambda$ ranging from 1 to 30.

These sets of tables, which are surprisingly expensive, are to be borrowed rather than bought.

B. J. Mason

Vector Spaces and Matrices

By Prof. Robert M. Thrall and Leonard Tornheim. Pp. xii – 318. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 54*s.* net.

WITH the exception of the final chapter, the book covers well-worn ground, but does so in an interesting and instructive manner, valuable from the teaching aspect. It builds up the instruction through levels of abstraction, from the concrete to the highly abstract. The reviewer has always held the view that an 'abstract' work on mathematics is unsuitable for the elementary student, especially if, as is so often the case, the work is totally, or almost, lacking in examples. Such students often imagine they understand such a work, but later find out that they did not understand in the least. They should be started on a concrete level, with plenty of examples, but not for too long, and then work up gradually to the heights of abstraction. This procedure the book under review carries out, and it is ably written; most of it is suitable for an honours degree course on the subject-matter.

The chapters, in order, are on: vector spaces, linear transformations and matrices, systems of linear equations, determinants, equivalence relations and canonical forms, functions of vectors, orthogonal and unitary equivalence, structure of polynomial rings, equivalence of matrices over a ring, similarity of matrices, linear inequalities.

The final chapter, containing sections on linear programming, the minimax theorem, and matrix games, is interesting in itself.

R. G. Cooke

An Atlas of Airborne Pollen Grains

By H. A. Hyde and K. F. Adams. Pp. xvi + 112. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1958.) 36*s.* net.

THIS book is the result of collaboration between a botanist and a medical man engaged in the study of pollen allergy. Its most striking feature is an excellent series of photomicrographs of pollen grains in their natural condition. These have been carefully selected to show the critical features of the grains in both optical section and surface view on a scale of about a thousand diameters. Although many technical terms are necessarily introduced, they are fully explained in the glossary. A well-arranged dichotomous key should make the book a valuable introduction to the study of palynology. Most of the grains illustrated and described are from wind-pollinated flowers, but a number of entomophilous forms are also included.

The book should be a valuable work of reference for the medical palynologist, who will find examples in it representative of all the indigenous pollen types of importance as well as a few exotics, such as *Ambrosia artemisiifolia*, the noxious American ragweed, occasionally found as an adventive in Britain. Apiculturists will also find the book interesting, as many of the anemophilous pollens are utilized by bees as well as the entomophilous forms. The book is admirably produced on glazed paper.

J. Hutchinson

Classics of Librarianship

Further Selected Readings in the History of Librarianship. By John L. Thornton. Pp. x + 203 + 8 plates. (London: Library Association 1957.) 24*s.*

THESE further selected readings in the history of librarianship include little of specific interest to the scientist or even to the technical librarian, save that each selection is accompanied by a biographical note on the author. Among the selections of general interest may be mentioned Sir Edward Bond's remarks on public libraries (from his address to the Library Association), H. Bradshaw's presidential address to the Library Association (1882); W. E. A. Axon's "Professorships of Bibliography"; H. R. Tedder on "Librarianship as a Profession"; T. Greenwood on "The Place of Public Libraries in our National Life"; J. C. Dana's presidential address to the American Library Association (1896); T. Mason's paper on Robert Watt, the author of the "Bibliotheca Britannica"; F. Pacy's retrospect of the Library Association at its fiftieth anniversary conference, 1927; W. W. Bishop on the "Backs of Books"; A. Esdaile's "Confessions of a Victorian"; and W. Blade's "The Enemies of Books". As Mr. Thornton admits, the selections are not all major contributions to major literature and are sometimes presented as typical of an author introduced for his contribution to librarianship in ideas or ideals or work. The biographical notes accordingly give the volume an interest and an appeal which may run outside the purely professional field represented by membership of the Library Association.

R. Brightman

BIOLOGICAL EFFECTS OF RADIATION

AT the Second United Nations International Conference on the Peaceful Uses of Atomic Energy only two of the sessions on isotopes and biology were devoted to what might strictly be called radiobiology. Health and safety in the atomic energy industry and advances in the use of isotopes (in biochemistry, physiology, medicine and agriculture) occupied considerably more of the time of the biological sessions. The First International Congress of Radiobiology had been held only one month earlier in Burlington, Vermont, U.S.A., and undoubtedly this Congress, which had been organized long before the Second Geneva Conference was announced, stole much of the radiobiological thunder. Some material was presented in essentially similar form to both meetings and might thus have reached a wider audience: but if the United Nations is to organize a third conference of this sort, a better integration with meetings of international societies is desirable.

It is convenient to think of the biological effects of radiation as falling into two main classes: somatic and genetic. No startlingly new concepts were expounded in the former, but in the relatively small field of genetics one saw the unfolding of a 'new look'. It has long been axiomatic to consider the induction of true point mutations of genes as strictly linearly proportional to the dose of the inducing agent—ionizing radiation—irrespective of the dose-rate of the radiation. W. L. and L. B. Russell (*P*/897) reported results of their many years work on the induction of mutation at seven specific loci in the mouse. The present indications are that the induction of mutations is not linear at all doses and not independent of dose-rate. Further work is necessary to improve the precision of the observations; for if confirmed, the results indicate that new assessments will be needed of the genetic hazards in a nuclear age.

The fundamentally simple but often tedious approach to the investigation of these genetic hazards is through scoring of point mutations of genes responsible for a single characteristic; but most of the qualities which constitute 'fitness' of an individual are determined by a multiplicity of genes. The Russells have made a first approach to investigation of fitness by scoring the size of litters and the longevity of offspring sired by an irradiated parent: both show reduction compared with controls. The 'fitness' of irradiated populations has also been investigated by Bonnier *et al.* (*P*/169) and Buzzati-Traverso and Scossiroli (*P*/1391) in the fruit-fly, *Drosophila*. The former found that, when there was strong selection pressure by reducing available food supplies, the adaptation to the effects of irradiation with each generation was quicker: it appeared that the increasing heterozygosity was balancing the induced deleterious effects. The Italian workers also found this increased adaptability of the irradiated population to unfavourable environments. The irradiation induced a variability which permitted a more rapid attainment of conditions of equilibrium. There is no conflict here with the accepted law that the induced mutations are mainly detrimental in themselves, but evidence continues to accrue that the rate of evolution is enhanced even with low doses of radiation (Burdick and Mukai, *P*/895).

Whereas man is certainly the ultimate object of study and the mouse is at present the nearest but *Drosophila* the usual model, invaluable information can be obtained even from bacteria, especially in the elucidation of chemical processes. Haas and Doudney (*P*/896) noted that mutation requires cellular metabolism and that starving the irradiated cell of nutrients diminishes the probability of mutation. Amino-acids and energy-sources are pre-requisites.

Of general interest to geneticists and cytogeneticists was the review by Dubinin (*P*/2074), presented by Prokofeva-Belgovskaya, indicating rapidly increasing activity by Soviet scientists in the fields which are generally regarded as orthodox.

When one turns to consider the somatic effects on the individual, it is found that interest is again directed to the prediction of hazard. Therefore, the relationship of dose to effect is one of the most important functions to determine. When there is but a single exposure to radiation, the objective is readily attained experimentally. For most effects the plot of effect versus dose is sigmoid; occasionally a linear relationship like the classical response for gene-mutation is obtained. In the latter case there is a tendency to invoke somatic mutation. There has recently, and perhaps especially in the recent report of the United Nations Scientific Committee on the Effects of Atomic Radiation, been a tendency to give more weight to linear relationships than the evidence justifies, for the confirmed examples are very few. Bond *et al.* (*P*/885) now report a further example; mammary tumours (adeno-fibroma and carcinoma, and fibro-adenoma and sarcoma) increased in Sprague–Dawley rats proportionately to the dose they had received. However, this linearity was obtained only by not scoring beyond ten months. There is a suggestion that the radiation was merely accelerating a natural event. Certainly somatic mutation alone could not be invoked to account for the result, since the manifestation of the tumour was shown to be dependent on humoral influences.

A linear relationship precludes a so-called threshold of dose below which no biological effects can be detected. Without attempting strictly to define the effect–dose relationship, Soviet scientists (Lebedinsky *et al.*, *P*/2068) announced the recording of the effects of very small doses of radiation. By electroencephalography, abnormalities in bio-electrical activity of the cerebral cortex have been seen with doses of the order of 1 r. A similarly sensitive system is claimed for the electroretinogram of the isolated frog's eye.

When one comes to the more difficult problems of interpreting the effects of fractionated doses or of continuous irradiation, the effect–dose relationship may be more complex. Leukæmia, a malignant disease much in the public eye at the moment and not infrequently induced by radiation, has been considered as due to somatic mutation. In mice, however, the results obtained by Mole (*P*/96) in two strains of mice are difficult to fit with this hypothesis, certainly in its simplest form. For equal accumulated doses the incidence of leukæmia within ten months was anything between 6 and 30 per cent: dose-rate or radiation-free time certainly was a relevant factor. Ford and Mole (*P*/98) also showed elegant pictures of the chromosomal changes found in these leukæmic cells.

Malignant disease apart, a general non-specific shortening of life-span has been attributed to the effects of radiation. It could be postulated that radiation, either as a large single dose or a multiplicity of smaller doses, could act as a non-specific stress to give this result. Curtis and Gebhard (*P*/912) found differences in the patterns of mortality of irradiated and non-specifically stressed mice: in their hands the latter did not cause shortening of life. Following single large doses of radiation to the whole body, the earlier deaths are considered by Maisin *et al.* (*P*/109) to be the sequelæ of irradiation of the lung, the intermediate deaths to irradiation of the head and the latest to irradiation of the abdomen. Lindop and Rotblat (*P*/292) also reported their preliminary results in a very large experiment designed to elucidate some of the problems of ageing. Some of the observed effects were startling, which suggests that confirmation with standard strains of mice is highly desirable.

Malignant tumours and shortening of life result from the administration of radioactive materials giving substantial radiation-doses, the pathological changes being related to the chemical characteristics of the material given and its sites of concentration. The report of Burykina *et al.* (*P*/2077) presented by Krayevsky gives details of the late effects produced by administration of fission products to experimental animals. The title of their communication suggests that the doses were small, which is true in terms of mass, but the tissue-doses were measured in kilorads. Lamerton (*P*/61) reviewed the problems associated with the setting of permissible doses of radioactive materials. He believes that the estimation of the radiation-dose with all its present shortcomings provides the most satisfactory criterion. He argues that for the induction of osteo-sarcoma there is almost certainly a threshold which must be many hundreds of rads. Much of the argument is based on the one comprehensive experiment so far carried out on the long-term toxicological effects of radioactive materials; some aspects of this work in Chicago relating to strontium-90 were given by Finkel *et al.* (*P*/911).

Whereas radiobiologists are rightly most occupied at the present time with small doses of radiation and delayed effects, there is still considerable interest in the large single dose such as might be received in an accident, or which might have to be incurred by a few to avoid harm to many. Studies have been aimed at conditioning the body to resist radiation-doses normally lethal. This has not led to any practical measure which could safely be applied, but it has led to a better understanding of the effects of radiation on the intact mammal. Hollaender *et al.* (*P*/898) summarized their latest advances in this field of chemical protection. They favour the view that the main function of these agents is neutralization of free radicals formed by ionizing radiation. In the case of other active agents, biological amines, van der Meer *et al.* (*P*/556) argue convincingly in favour of tissue hypoxia. The role of oxygen in affecting the response of cells and tissues to ionizing radiations has been widely studied and Gray *et al.* (*P*/293) reviewed some of their recent work.

In addition to exploring the possibilities of protection against lethal doses, therapy of the animal lethally irradiated has been actively investigated. Hollaender *et al.* (*P*/898) reported their results of administering blood-forming cells which recolonize the marrow spaces of the irradiated animal. This grafting of homologous tissue may lead to undesirable late reactions. Barnes *et al.* (*P*/97), by cytological methods, have noted in some of these homologous chimæras a reversion of the marrow cells back to host type; apparently the cell clones with the greatest physiological competence, be they of normal donor or radiation-damaged host, ultimately predominate. In both laboratories these therapeutic exercises have involved administration of living cells to the irradiated mouse; but cell-free chemical agents are still being tried. Soska *et al.* (*P*/2121) claim reduced mortality from irradiation following administration of deoxynucleotides (but not following deoxynucleosides). Similarly, Panjevac *et al.* (*P*/490) found improved survival from the administration of deoxyribonucleic acid or ribonucleic acid from homologous spleen or liver, but not from testis.

Experimental work on the intact mammal has been chiefly the theme of this review. This does not mean that radiobiologists are now getting away from the simple systems—the root of the broad bean, the yeast cell and the bacterium. Many of the papers presented were concerned with the basic lesion in these test objects. Equally there were a number of papers primarily chemical, particularly on the chemistry of the nucleic acids; and a paper from the U.S.S.R. on effects of radiation on bio-lipids (Tarusov *P*/2248) indicates the continued interest in that country in the effects of radiation in the nervous system.

The collected papers will, of course, be published by the United Nations Organisation as the Proceedings of the Second Conference on the Peaceful Uses of Atomic Energy.

J. F. Loutit

PHYSICS OF QUANTA AND PARITY

The opening session of Section A (Physics) of the British Association meeting in Glasgow on August 28 was devoted to papers presented by members of the Department of Natural Philosophy in the University of Glasgow. The research work of this Department is mainly concerned with studies of photomeson production and photodisintegration, utilizing the high-energy quanta which are provided by the departmental 340-MeV. synchrotron. Three of the papers presented at this session were concerned with experimental investigations of this type; the fourth, by Prof. J. C. Gunn, professor of theoretical physics at Glasgow, discussed the important discovery during the past year of the non-conservation of parity.

In the opening address, Prof. P. I. Dee traced briefly the development of the concept of quanta from the original suggestion made by Planck, in 1901, to explain the conflict between the experimental results relating to the distribution of energy in black-body radiation and the straightforward predictions of classical theory in terms of the principle of equipartition of energy, which had been so fruitful in the development of the kinetic theory of gases. Compton's demonstration in 1923 that the wave-length changes which occur when X-rays are scattered by electrons could be quantitatively explained by treating the problem as a simple collision process, satisfying laws of conservation of energy and momentum, between a quantum of radiation and an electron, showed that the quantum concept applied to much wider fields than those in which absorption or emission of radiation were concerned.

The whole of the physical world, as we know it, may be regarded as comprised of matter and radiation. It is natural, therefore, that the interactions between the elementary quanta of radiation and the basic constituent particles of matter, neutrons and protons, should constitute one of the frontier problems in modern physics. In processes such as these, mesons are created, and in view of the part played by these particles in relation to nuclear forces, experiments of this nature are therefore not only fundamental to the understanding of the basic phenomena of interaction between radiation and matter but also shed light upon the structure of atomic nuclei.

Recent experiments at Glasgow and elsewhere upon the photoproduction of π^+ and π^- mesons in hydrogen and deuterium permit the comparison of the cross-sections for the production of these particles in reactions of quanta with protons and neutrons, respectively. In these experiments the important principle that nuclear forces are independent of charge seems to receive good confirmation. Similar experiments upon the relative production of $\pi+$ mesons in hydrogen and deuterium provide information upon the dependence on spin of the photomeson production interaction. Studies of π^0 production by quanta in helium suggest that in this process the close proximity of other nucleons has little effect upon the primary interactions between the quanta and the elementary nucleons.

The idea of quantization in physics applies, of course, in a much more profound and general manner than merely in relation to the electromagnetic radiation. The concept of structure in the intervening medium was introduced long ago by Faraday to explain the forces between electrical charges. This concept of the 'field' in physics has now assumed a very wide significance. It is even possible that all the elementary particles of matter, the protons, neutrons, mesons, etc., consist essentially of particular quantized states of a general field. Of what this field consists no one at present can say ; indeed, it may not yet even be sensible to inquire.

In the following paper, Mr. J. M. Reid (Glasgow) gave an account of recent work upon the disintegration of nuclei under irradiation by high-energy quanta. Experiments of this nature have been made with quanta over a wide range of energies, from a few MeV. up to about 300 MeV. At the lower end of this energy region the main feature in the case of all nuclei is a broad or 'giant' absorption resonance which reaches its maximum at a quantum energy of about 20 MeV. and has a width of about 6 MeV. This resonance has been explained as a collective oscillation in which all the protons in the nucleus move together in one direction while all the neutrons move in the other. Such a picture can only provide a rough indication of nuclear behaviour, since it omits all details of the motion of the proton and neutron 'fluids'. Indications have been found of departures from the bell-shaped resonance curve which such a model predicts. In particular, a cloud-chamber investigation at Glasgow has shown strong absorption of quanta of very sharply defined wave-length at the low-energy end of the 'giant' resonance.

A similar cloud-chamber experiment has confirmed a result obtained in American laboratories by other techniques. This concerns the energy region above the 'giant' resonance where, by virtue of its short wave-length, the quantum energy is so localized that only part of the nucleus is affected. A sub-unit greatly favoured in such interactions has been shown to be a single proton–neutron pair. These two nucleons are, as a result, violently ejected as a free neutron and proton, apparently uninfluenced (at least in a large number of cases) by the presence of the rest of the nucleus. Similarly, when this happens, the rest of the nucleus continues in its state of motion despite the plucking of the pair of particles from within its volume. This seems to open up the possibility of investigating, in a more direct way than hitherto, the nature of the internal motion which is occurring within the atomic nucleus.

Dr. J. G. Rutherglen (Glasgow) delivered a lecture devoted to the techniques and uses of millimicrosecond measurements, which have now assumed great importance in atomic and nuclear investigations. For example, the new fundamental particles which have been discovered in the past ten years are all unstable and only live for times between a microsecond and a ten-thousandth of a microsecond. There are many important processes in nuclear physics which take place in comparable, or even shorter, times than this. Measurements of very short time-intervals are therefore necessary to investigate the properties of these particles and processes which are fundamental to our understanding of the basic properties of matter.

The electronic techniques involved in measurements in the region down to a microsecond were developed to a very high degree during the Second World War by the needs of radar and similar applications. At that time the measurements in the field of nuclear physics were limited to about a microsecond by the properties of Geiger counters and similar devices which were then available for the detection of nuclear radiations.

During the past ten years both the detectors and the electronic techniques have been improved in regard to time resolution by a factor of the order of one thousand, so that it is now possible to measure time-intervals as short as one millimicrosecond and to detect even shorter differences in time. The main advance in the detection technique has been the development of the scintillation counter, in which part of the energy of the nuclear radiation is converted into light in a block of transparent material, and the light flash is converted into an electrical pulse by means of a photomultiplier. Techniques of this nature are now commonly employed in many nuclear investigations. For example, $\pi+$ mesons are often identified by measuring the time-interval, of the order of 1/50 microsecond, between the pulse due to the arrival of the $\pi+$ meson and that due to the $\mu+$ meson which results from its decay. Again, the life-times of short-lived nuclear states may in some cases be measured in similar fashion, but the order of time resolution which is so far possible is not yet sufficient for very comprehensive investigations in this particular field.

The second main topic at the opening session was "The Non-Conservation of Parity", which was very clearly presented both in respect of its difficult primary concepts and of its fundamental influence upon basic physical principles by Prof. J. C. Gunn. The recent discovery, following a suggestion of Lee and Yang, that parity is not conserved in certain weak elementary particle interactions, represents a revolution in our ideas of space and time in some ways comparable with the introduction by Einstein of his special theory of relativity in 1906. The essence of Einstein's idea was that the laws of all natural phenomena should be the same for all observers in uniform motion relative to each other. It was automatically assumed that along with this invariance of the equations of physics for transitions to moving reference frames would go invariance to reflexions in space and time. In particular, invariance to reflexions in space is mathematically expressed as the conservation of parity. Put in its simplest form, such invariance simply means that the mirror-image of any physical or chemical system shows a behaviour which could occur in accordance with natural laws in the real world. Effectively, the scientist looking at any experiment cannot say whether what he is seeing is the real thing, or a reflexion in a mirror.

It is indeed true that parity conservation, or invariance to reflexion, is observed for all the more ordinary physical processes—the processes controlled by electrical forces, which account for the physics and chemistry of everyday life, and the processes of more recent interest controlled by nuclear interactions. Of course, local conditions, as, for example, biological systems on Earth, may result in only, say, the right-handed form of some molecule or structure occurring, its left-handed mirror-image being absent. However, this is only a local phenomenon and the left-handed variety is, in principle, quite possible.

This is how things rested when Lee and Yang made their proposal that, though invariance to reflexion holds for the strong electromagnetic and nuclear interactions, it might not hold for weak interactions, such as those responsible for β-decay of nuclei and other decay processes of the unstable particles found in high-energy physics. Their hypothesis has been brilliantly confirmed by experiments, both on β-decay and on the decay of unstable particles, and it is now established that parity conservation is violated over the whole range of weak decays. For example, the neutrino emitted in β-decay always spins like a left-handed screw along its direction of motion. The mirror-image of this would be a right-handed screw neutrino and this is not found to exist.

This left-handedness of the neutrino provides a means by which the physicist can now discriminate between a real and a looking-glass world. An important reservation must, however, be made—the mirrored image of a decay experiment with ordinary matter is impossible as a real process for ordinary matter, but, according to current belief, it represents exactly how anti-matter would behave. Thus, if, possibly in other galaxies, there are worlds of anti-matter their neutrinos are right-handed in our sense. In view of the possible existence of such worlds, no universal significance can be expressed to left-handedness. We might indeed say that, like that of biological systems, the handedness of the neutrino is an environmental character, but the environment is a wide one, consisting of all ordinary matter.

MICROWAVE PHYSICS

THE final session of Section A of the British Association meeting in Glasgow was held on September 3, and was devoted to the subject of microwave physics. It was appropriate that the chair should be taken by Dr. B. J. Mason, for he has acted as recorder of this Section for a number of years and now retires from this onerous and responsible position. The meeting warmly expressed their appreciation of his work.

There were three speakers, and it was soon clear that their papers had been planned to try to give, for the non-expert, some indications of the remarkable developments which have occurred in microwave physics since the War. The first speaker, Prof. K. W. H. Stevens, of the University of Nottingham, began his lecture by giving an elementary account of what is meant by electron spin resonance. The magnetic moment associated with the spin of the electron has two equilibrium positions in a magnetic field, of different energies. The moment can be turned from the lower one to the higher one by supplying a quantum of electromagnetic radiation of the right magnitude. For a free electron the relation between the size of the field and the wave-length of the radiation is $H\lambda = 10 \cdot 70$, where H is measured in kilo-oersteds and λ in cm. For fields of order 3×10^3 oersteds, a convenient laboratory magnitude, λ is approximately 3 cm., which is in the microwave region. Very good oscillators and components are available for these wave-lengths, as a result of war-time radar developments.

Although all substances contain many electrons these are usually paired off, with spins opposed. Such pairs do not show electron spin resonance. Thus to demonstrate the resonance it is essential to work with substances containing unpaired electrons, and it seemed, at one time, that this would provide a serious limitation to the use of the spin resonance technique. This has not in fact proved to be the case, for it is now clear that unpaired electrons occur very widely, and one of the great virtues of the technique is that it can investigate these electrons in detail and thus throw light on problems which are of considerable interest and which are not always easily investigated by other means.

This aspect was particularly emphasized in the second part of Prof. Stevens's talk and by Dr. D. J. E. Ingram, of the University of Southampton, who followed him. The main idea is to use the electron magnetic moment as a probe to find out something about the electron motion. In the course of its motion, the electron may move from one atom to another, in which case there is the possibility that it may interact with the spins of the nuclei around which it moves and thus give rise to resolvable hyperfine structures. Thus, in favourable cases, as the electron explores the various atoms in a molecule or solid, so it gives, by means of the resonance technique, a record of its path. A number of examples were given, and it would seem of value to describe a few of these in some detail. If one takes a mixture of hydrogen peroxide and *iso*propanol and exposes the system to ultra-violet radiation the hydrogen peroxide is broken into two hydroxyl radicals, which are highly reactive and have unpaired spins. They show electron spin resonance. As they now move about in the mixture they attack the *iso*propanol molecules, and transfer their unpaired electrons in exchange for hydrogen atoms, the hydroxyl radical becoming stable water molecules. The free radical formed from the *iso*propanol now shows a resonance which has the typical features expected when an unpaired electron explores six hydrogen atoms. In this way not only is it possible to study how the hydroxyl radicals attack another molecule but it is also possible to learn something about where the transferred electron goes to in the process. Another topical example of a similar nature concerned the existence of free radicals in tobacco smoke. Dr. Ingram reported a preliminary experiment in which he had condensed tobacco smoke at liquid-nitrogen temperatures and had then investigated the condensate. This was found to have a very high concentration of free radicals. The previous example had given an indication of how reactive free radicals are, so it was not surprising to find that he was questioned from the audience about how long such free radicals may exist. This is not known yet, but it could be of the order of seconds. It is thus a sobering thought that every puff of tobacco smoke may transfer to the lungs a large number of very reactive free radicals, and it is clear that this sort of result, though preliminary, may be of considerable importance.

To illustrate the diversity of phenomena which are currently being investigated by this technique, we may mention briefly the following topics which were all described. In semiconductors it is valuable to be able to investigate the properties of minute amounts of impurities, without destroying the samples. These impurities frequently have unpaired electrons associated with them, which can be observed. In coals and oils at about 600° C. it is found that there is a high concentration of unpaired electrons. This may have a bearing on the burning of fuels in internal combustion engines. In polymerization an unpaired electron is found on the end of the polymer and the growth process can be studied. Radiation damage in solids often gives rise to centres which show spin resonance, and the detailed investigation of these, and the comparison with other physical properties, such as colour, are proving of considerable interest.

The third paper was given by Mr. I. M. Ross, of the Services Electronics Research Laboratory at Harlow. His theme was different from that of the previous two speakers, for he chose to discuss the impact which the resonance technique has made on microwaves. A few years ago this could have been a very short paper, for it would be true to say that until very recently the resonance workers have made use of the microwave valves and techniques but have contributed very little in return. However, the recent developments in 'masers', an acronym formed from the initial letters of Microwave Amplification by Stimulated Emission of Radiation, has changed the situation drastically. Two problems which face the microwave engineer are (*a*) how to amplify microwaves and (*b*) how to reduce the noise background in the amplifiers and so increase the sensitivity of the receivers. While masers may not provide the complete answer to his problem they are certainly of considerable promise.

The main idea in a maser is the reverse of that used in a resonance experiment. In resonance use is made of the two spin-levels, and absorption of energy occurs when an electron goes from the lower level to the upper level. If the reverse process occurs, energy is given out. In thermal equilibrium there are always more electrons in the lower state than in the upper state, so that, although radiation may persuade those in the upper states to de-excite, it also persuades those in the lower state to excite, and there is always a net absorption of energy. To get a net emission of energy (for this is what is needed for amplification of microwave signals) it is necessary to have an arrangement whereby one starts with more electrons in the excited state than in the ground state. For continuous amplification this situation must be maintained, but for pulse amplification the emissive state need only be obtained while the pulse is actually being amplified. The problem of getting more electrons (or atoms) into the upper than lower state has caught the imagination of a number of physicists, and a variety of ingenious suggestions have been made and tried.

One of the simplest to understand is that which uses a beam of ammonia molecules, though this does not use the spin energy difference. Ammonia molecules have two closely spaced energy-levels and if one takes a beam of ammonia molecules it is possible to split the beam into two, one containing only molecules in the lower state and the other containing only molecules in the upper state. The molecules in the second beam can then be used to provide energy, by de-exciting them. This system does not lend itself to microwave amplification because of its narrow band-width, but may well provide us with a frequency standard which is more stable than any previously obtained. To increase the band-width and to make amplifiers instead of oscillators it is necessary to go to solids, and then there is no possibility of geometrically separating the excited atoms or molecules, so other methods must be sought. One very ingenious device uses three energy-levels. In this, energy is provided by microwave radiation to promote atoms from the lowest to the uppermost level. Provided that enough power is available it is possible to equalize the populations of these two levels, so that the upper level has gained atoms at the expense of the lowest level. The third, intermediate level, takes no direct part in this, and it is possible to reach a situation in which more atoms are in the uppermost level than are in the intermediate level. A relative population reversal has occurred and emission instead of absorption can be achieved on irradiating the system with microwave radiation corresponding to the energy difference between the middle and upper levels. There are a number of problems involved in actually making a device which works on this principle, as can perhaps be inferred from the fact that one of the most promising maser materials is ruby, which is an impure form of aluminium oxide, containing chromium impurities. The aluminium oxide provides a very good medium in which to have the paramagnetic chromium ions.

A somewhat similar type of amplifier is that which has been known since the days of Lord Rayleigh, and which has recently come into its own in the microwave field. This is the so-called parametric amplifier, and in essence it uses a time-dependent reactance to couple together two resonant systems, in such a way that energy is fed from the reactance variation to the resonant systems. The microwave engineering of this is quite complicated, as was evident from the slide shown, but such devices have been made to operate using either ferrites or garnets as the active material.

In the solids no electron beams are used in obtaining the amplification, and the only sources from which thermal fluctuations can arise are in the devices themselves, in their associated circuitry and from the driving oscillator. The masers have so far only been operated at liquid-helium temperatures (though it is possible that they may be usable at higher temperatures), and have extremely low noise. The parametric amplifiers will work at room temperature, which is a distinct advantage, but they are noisier than the masers, but comparable if not better than any other types of microwave amplifiers.

The immediate applications for which these amplifiers could be very valuable include their use in radio astronomy to detect the microwave radiations from outer space, in communicating with and observing Earth satellites and in increasing the sensitivity of radar systems.

The field of microwave physics which looked a few years ago to be a very specialized and limited one is in fact broadening out in much the same way that nuclear magnetic resonance has developed. Electron spin resonance apparatus is no longer to be found in a few university laboratories, for a number of industries and hospitals have realized its potential value, and there seems every likelihood that its value will be more widely appreciated in the next few years.

In view of this year's theme of the Association, it seemed appropriate to close Section A with an account of the way in which a rather specialized laboratory technique promises to become a powerful tool for industry, and it will be a very good example of the value of pure research to industry if the maser developments have their expected impact on the microwave industry.

K. W. H. STEVENS

TRENDS IN METALLURGY

SIR ANDREW McCANCE in opening, on September 1, the session before Section B (Chemistry) of the British Association meeting in Glasgow, dealing with "Some Recent Trends in Metallurgy", reviewed in broad outline the progress made in the scientific world during the past few years and emphasized the important part that metallurgy had played in making this possible. He said the standard of living of industrial countries was indicated very largely by the steel consumption per head of population. By this standard the United States led the world with Germany and Britain 20 per cent and Japan 85 per cent below the American standard. British production per man employed had increased by 55 per cent since the War. This truly remarkable achievement had been brought about by an increase in the size of the producing unit, by improved equipment and by advances in technical knowledge such as the use of oxygen in steel-making.

The impact on metallurgical practice of the ever-increasing demand for materials to withstand higher temperatures and pressures had been very marked and he felt that the difficulty of finding metals of such strength to withstand working temperatures of 800–900° C. would cause a definite hold-up in progress. Though it was dangerous to argue from analogy, and we had only the most elementary guide to a pathway through the wilderness of ignorance, it was not out of place to point out that the most successful high-temperature alloy to-day was based on nickel with a melting point of 1,450° C. and chromium with a melting point of 1,850° C. The science of metals had lagged behind the technology of their use, and more imaginative work on factors contributing to their strength properties was a field offering great practical possibilities.

Creep and brittle fracture were two interesting problems of a fundamental nature, and though they had given rise to innumerable papers and much discussion yet remained in about the same state of advancement as they were ten years ago. In the case of brittleness it would appear that the results depended just as much on the type of test as on the nature and condition of the material being tested. A completely new approach to this problem would be welcome.

In the science of metals progress had resulted from the work of physicists rather than of metallurgists, and the fascinating developments in the use of semiconductors like germanium and silicon and the immediate applications to which inventions based on these discoveries had been put are outstanding achievements. However, during the past ten years much had been written about dislocations and they had been brought into the explanation of every conceivable property that metals possess. Sir Andrew regretted, however, that in many of these explanations there was more mathematics than physics and thought it doubtful if any real quantitative contribution had been made to our knowledge of the properties of metals by the dislocation theory, although it had contributed to our qualitative understanding of why metals behave as they do.

In a discussion of some recent applications of chemistry to metallurgy, Prof. R. Hay and Dr. P. T. Carter described the development of the modern highly mechanized iron blast furnace. Most of this development had resulted from the efforts of the engineer, but more recently, the metallurgist, using a chemical approach, had made important contributions. Investigations into the rate of reduction of different ores had led to the use of properly sized burdens, and petrological studies of the changes occurring during sintering into lump form of the fines produced during crushing, or blown out of the top of the furnace, had shown that the formation of fayalite (Fe_2SiO_4) caused a serious decrease in reducibility. Later work showed that fayalite formation could be avoided if the iron oxide particles could be bonded together by diffusion in the solid state, without melting occurring.

When melting could not be prevented, fayalite formation could be avoided by adding lime to form calcium silicate. In smelting lean ores, the incorporation of lime in the sinter mix ensured at the same time intimate mixing of the gangue and flux, and easy reducibility of the iron oxide, and now all the ore can be converted into easily reducible sinter, with a reduction of about 30 per cent in coke requirements.

Recent research into the constitution and properties of blast furnace slags was also described. A knowledge of their viscosities and melting points, and of their ability to control impurities in the iron such as sulphur and silicon, had contributed considerably to improved blast furnace practice in recent years.

The important effect of impurities on metal properties was described, and methods for their removal were discussed. Selective oxidation of impurities was well known, and recent compilations of thermodynamic data on metal/oxide systems allowed quantitative assessment of such methods. Selective chlorination could also be used, as in the removal of zinc from lead, and it was suggested that recent improvements in fluorine technology might result in similar applications for fluorine.

These methods introduce elements which may be as harmful as the original impurities. After selective oxidation, suitable deoxidizers—the choice being determined by cost, solubility and the formation of easily removable products—could be used, but the metal still contained small amounts of deoxidizing elements. The nearest approaches to the production of pure metal had been obtained by complicated and protracted chemical methods, or the comparatively simple zone-melting techniques developed by Pfann. Remarkable degrees of purification were possible, and in the case of germanium, impurities which affected its electrical properties could be reduced to less than one atom in 10^{10}. Similar degrees of refining were possible with gallium and antimony, and most of the impurities could not be detected even by spectroscopic methods. Problems of contamination from the container used in the zone refining of reactive high melting point metals such as silicon, iron, germanium, etc., had been overcome by the use of floating zone techniques, in which no container was used, the molten metal being held in place by its own surface tension. Iron prepared thus showed ductility even at temperatures approaching 0° K.

Gaseous impurities were more difficult to remove, but recently, induction vacuum melting and consumable electrode vacuum arc melting had been successfully applied to the production of large ingots. The former had been used particularly for the nimonic type of alloys, since it afforded close control of composition, and for certain special steels, and ingots up to 2,000 lb. had been made by this process. Consumable electrode processes in which air-melted electrodes were consumably remelted in water-cooled copper crucibles were now an integral step in the production of titanium, zirconium, molybdenum and many special alloy steels. They were less costly than vacuum induction melting, and could make ingots up to six tons.

Both processes were costly for the large tonnages usually encountered in steel-making, but vacuum degassing in the mould, which was cheaper and simpler, had resulted in considerable reduction in the hydrogen, nitrogen and oxygen contents of steel.

The newer metals in industry were discussed in a paper presented by Dr. H. M. Finniston and Dr. P. Murray. They pointed out that the newer metals fell into two groups. The first had a specific purpose for which it was difficult to see applications outside the field for which they were originally developed. To this group belonged uranium, thorium and plutonium, with perhaps germanium and silicon. The second group, which included titanium, zirconium, beryllium, niobium and molybdenum, was likely to have a wider field of application. For example, zirconium has very good corrosion resistance and niobium has potentialities as a high-temperature creep-resistant material.

There were, however, several similarities between these metals. The extraction processes, because of the stability of their oxides, were all relatively complicated. All these metals were reactive and in many cases their physical properties, especially ductility, were adversely affected by small concentrations of gaseous impurities such as hydrogen, oxygen and nitrogen. This had led to developments in vacuum melting and casting techniques. In the case of the very high melting point metals thorium and niobium, powder metallurgy techniques had been employed with advancement in the use of high-pressure and high-temperature vacuum-sintering operations. The physical metallurgy of some of these metals was complicated due to the number of phase changes and to their alloying behaviour not conforming to the pattern of the more common metals.

In discussing the first group of metals the authors pointed out that the most interesting and important feature of uranium was its behaviour as a fuel in a reactor when bombarded with neutrons and this had introduced a completely new problem in metallurgical studies. At temperatures up to 350° C., growth occurred due to change in crystal shape, and at temperatures higher than 350° C. swelling of the metal took place. The former—generally referred to as 'wrinkling'—occurred in material with a marked texture and could be overcome by obtaining a randomly oriented fine-grained structure prior to irradiation. The latter effect was due to the nucleation of bubbles of the inert gases, krypton and xenon, produced by fission. This was accompanied by a marked decrease in density of the metal.

Plutonium, the synthetically produced metal from the uranium in the reactor, was metallurgically unique in that it existed in six different phases between room temperature and its melting point (630° C.). Two of these phases exhibited negative coefficients of thermal expansion.

Of the second group of metals titanium was the most extensively used, largely as a structural material in alloy form in the aircraft industry. In the range 200–400° C. titanium alloys possessed a better strength/weight ratio than either of its competitors, aluminium alloys and alloy steels. Above 400° C. alloy steels were superior. Zirconium, although a high melting point metal, was also disappointing in that at medium temperatures its strength, like that of titanium, was not very good. All the early zirconium metal contained small quantities of hafnium, but although this metal is an identical twin of zirconium in chemical behaviour, in the nuclear reactor there is no such similarity. Though zirconium was virtually transparent to neutrons, hafnium absorbed so many that it is considered a most suitable material of construction for reactor control rods. Zirconium is primarily a sheathing material in pressurized water reactors where good corrosion resistance in water at temperatures up to 325° C. is essential. Zirconium alloys have been developed with corrosion-rates as low as 1/5,000 in. per annum.

Knowledge of beryllium and its properties has advanced considerably over the past ten years largely as the result of its potential applications in nuclear reactors. It has been used for many years as an alloying element particularly with copper. The metal is extracted by two methods. The principal method is the thermal reduction process using magnesium reduction of beryllium fluoride at temperatures above the melting point of beryllium. The metal forms as globules which float to the surface of the bath. For removal of magnesium fluoride, melting *in vacuo* or under partial pressure of argon is employed. The other method of production uses the electrolysis of fused salts, mostly the eutectic mixture of sodium and beryllium chlorides, although fused fluorides have been used. Beryllium can be extruded over the temperature-range 400° C.–1,000° C. Sheathing of the metal provides a solution to the health hazard, iron being the usual sheathing metal. A technique using the combined operations of powder metallurgy, consolidation and extrusion has been successfully developed. Beryllium is associated with inherent brittleness due to cleavage occurring along the basal plane. Attempts have been made to produce very pure beryllium. Zone refining has given disappointing results; but evaporation of vacuum-melted high-purity electrolytic flakes has yielded a very pure metal having an oxygen content of 10 parts per 10^6. Such small crystals as were tested fractured in the normal fashion. Above 400° C. the mode of failure changes from transcrystalline to intercrystalline; but the reasons for this change are unknown. In spite of such difficulties the metallurgist has succeeded in developing a wide variety of fabrication techniques and has also succeeded in joining beryllium to other metals and to itself.

Several methods have been proposed for the production of niobium such as electrolysis of fused potassium niobium oxyfluoride, the reduction of the oxide by the carbide and the reduction of potassium niobium fluoride by sodium or magnesium. The main method of consolidation is sintering of cold-pressed compacts. Niobium metal is an excellent 'getter' absorbing both oxygen and nitrogen rapidly on heating. Hydrogen is also absorbed at temperatures up to 500° C. The elimination of non-metallic elements is essential for the production of ductile metal. The three main methods of purification which can be utilized during sintering are: (1) low-temperature eliminations of hydrogen up to 1,100° C.; (2) the formation of carbon monoxide above 1,650° C.; (3) the elimination of oxygen probably by volatilization of an oxide of niobium at temperatures above 1,900° C.

An important factor in attaining sound bars is the correct grading of the powder. Too fine powder sinters too quickly at the surface, resulting in retention of the gases and ultimate formation of gross internal voids. The sintered bar is cold forged and re-sintered at a maximum temperature of 2,300° C. The resulting pure metal is ductile and can be formed cold by most of the usual methods. Hot forming is not possible owing to the pick-up of gases resulting in embrittlement. At present its only industrial use is in nuclear reactors as a canning material. If alloy development succeeds in realizing the potentialities of niobium as a high-temperature creep-resistant material and can overcome its poor oxidation resistance the field of possible application will be widened considerably.

In the final paper Dr. N. P. Inglis and Mr. J. B. Cotton discussed the corrosion behaviour of tantalum, niobium, titanium, zirconium and beryllium. All these elements readily form oxides, and this in part is a factor in their very resistant behaviour under a wide range of conditions. The oxide film can prevent further attack provided this film is very closely bonded to the metal. Investigations of the attack of various solutions ranging from hot fuming sulphuric acid through hot neutral salt solutions to hot strong sodium hydroxide solutions on these metals had shown that tantalum was the most resistant, being closely followed by niobium, while beryllium was attacked by all the corrosive media. Titanium had good resistance to neutral chlorides and it was estimated that titanium sheet of the thickness of a postage stamp would take four thousand years to disappear in sea water. Titanium, though not nearly so resistant to attack as tantalum, was much cheaper and showed fair resistance to non-oxidizing acids. This suggested further examination of the possibility of forming protective films to raise its resistance to that of tantalum, and it was shown that the growth of oxide films could be stimulated by slightly raising the oxide potential of the metal when in contact with the corroding medium. The method of raising the potential was not important, provided its value exceeded a certain critical value. Titanium could be protected by connecting it to a more noble metal such as platinum or carbon. This was shown with the aid of cine-film in which the behaviour of a piece of titanium without protection was compared with that of another piece to which a protective potential was applied. Another example of protection was shown in which titanium with an extremely thin surface-film of platinum and another piece without such protection were immersed in a current of sea water.

R. Hay

A NOVEL TYPE OF METAL-PROTEIN COMPOUNDS

By Prof. K. H. GUSTAVSON

Garverinäringens Forskningsinstitut, Stockholm

All proteins are capable of binding metal ions, but the extent of binding and the stability of the metal-protein compounds vary greatly both with the nature of the metal ion, the nature of the protein and its net charge[1]. The transition group elements possess the greatest affinity for proteins generally and form the most stable compounds[1]. Positively charged polynuclear chromium complexes, such as  $(\mathrm{Cr}\overset{\mathrm{O}}{\underset{\mathrm{SO_4}}{\diamond}}\mathrm{Cr})^{2+}$, are held very firmly, so that no dissociation of the metal-protein complexes is detectable. The co-ordinate bond formed is largely covalent. The chromium complexes are potent cross-linking agents, stabilizing the protein. Thus, collagen binds basic chromium sulphate tenaciously; a reaction utilized in the important process of chrome tanning of leather. The chromed hide resists the action of boiling water and proteolytic enzymes. It is now generally considered[2] that in the initial reaction the cationic chromium complexes discharge the carboxylic ions of the protein. The electro-neutralization of the charges of the components of the system is followed by penetration of the carboxyl groups into the chromium complex, which results in the formation of co-ordinate-covalent bonds of great stability between the carboxyls and the chromium atoms of the complex.

Chromium-collagen compounds. Chromium is an exceedingly versatile metal so far as the formation of complexes goes. In aqueous solution of basic sulphates, polynuclear complexes with positive and negative electric charge as well as uncharged ones may be present simultaneously. The degree of affinity of the ligands for the chromium atom governs the nature of the complexes formed. Apart from the common type of cationic chromium-carboxyl compounds, other combinations are known, such as compounds with anionic chromium complexes attached to the ε-amino groups of the lysine residues and the guanidyl group of the arginine residue. These chromium-collagen complexes do not attain the exceptional stability possessed by the normal carboxylate type. Furthermore, it has been suggested that the hydroxy group of the hydroxyproline residue participates in the binding of non-ionic sulphito-sulphato-chromiates by collagen[2]. The present article outlines the reaction of neutral chromium complexes present in extremely basic chromium perchlorates with collagen. This reaction leads to the formation of an entirely new type of metal-protein complexes in which the uncharged chromium complexes are attached to the protein through its non-ionic keto-imide groups. Judging by the stabilization obtained by the fixation of these chromium perchlorate complexes, they cross-link the protein units. This novel class of metal-protein compounds should appear to be of general chemical interest, particularly from the points of view of the behaviour of proteins and complex chemistry.

The basic chromium perchlorates corresponding to the empirical formula: $Cr_2(OH)_{6-n}(ClO_4)_n$, where $n \geqslant 4$, their composition designated as per cent acidity $\left(\frac{n}{6} \times 100\right)$ in the following, contain in dilute and moderately concentrated solutions only positively charged complexes, free from ClO_4^- groups. By increasing the number of hydroxyl groups, stable aqueous solutions are obtained, containing compounds of the type $Cr_2(OH)_{6-n}(ClO_4)_n$, with $n \leqslant 2$. Most of these complexes do not migrate on free electrophoresis and do not react with ion exchangers. Thus, solutions of the 33 per cent acid perchlorate contained about 65–70 per cent of uncharged complexes and 30–35 per cent of cationic ones. The composition of the complexes first mentioned corresponds to the formula $(Cr_2(OH)_5ClO_4)_m$, and of those last mentioned to $Cr_2(OH)_2(ClO_4)_4$. The average molecular weight of the 33 per cent acid perchlorate, estimated by measurement of diffusion, indicates values of m equal to 2 or 3. The purely cationic complexes of the 67 per cent acid salt contain two chromium atoms on the average[3]. These react with collagen in the usual way, attaching themselves to the charged carboxyl groups of the protein. The neutral chromium complexes of the extremely basic perchlorates show an entirely different type of reaction with collagen. A résumé of some results obtained on investigating the mechanism of their fixation by hide protein follows. Detailed accounts of these researches will be given elsewhere.

Table 1

No.	Substrate	67 per cent acid chromium-perchlorate (m.equiv. chromium fixed by 1 gm. collagen)	33 per cent acid chromium-perchlorate m.equiv. chromium fixed by 1 gm. collagen	(Per cent acidity of chromium-collagen-compound)
1	Hide powder (H.P.)	2·1	4·4	27
2	Heat-denatured H.P.	2·2	7·9	20
3	Esterified H.P.	0·3	2·7	—
4	Deaminated H.P.	1·8	4·9	25
5	N-acetylated H.P.	2·0	4·2	—
6	N- and O-acetylated H.P.	1·9	5·6	—
7	H.P. pretreated in 2 *M* $NaClO_4$ solution for 7 days	2·4	9·1	18
8	H.P. tanned with tannic acid; 92 per cent tannin fixed by collagen	1·5	0·3	—
9	Polyamide	0·1	3·4	17

The solutions of the extremely basic chromium perchlorates, 33 per cent acid or less, were prepared by addition of sodium hydroxide, in 10 per cent solution, to a solution of the 67 per cent acid perchlorate, which in its turn was obtained by boiling freshly precipitated hydrous chromic oxide (from hexaquochromium chloride) with the required amount of perchloric acid. The final solutions, containing 1·00 equiv. chromium per litre, were at least six weeks old when used. The *p*H values were 3·4 and 2·9, respectively.

The complex composition of these solutions of the 33 and 67 per cent acid chromium perchlorates was ascertained by the ion exchange method[2], employing the sodium salt of 'Dowex-50' and the perchloric acid salt of 'Amberlite IRA-400'. The 33 per cent acid compound contained 72 per cent uncharged complexes of 17 per cent acidity, the rest being cationic. The 67 per cent acid chromium perchlorate contained positively charged complexes only.

Reaction with collagen and modified collagens. In Table 1, results on the irreversible fixation of these two chromium perchlorates by specimens of intact collagen and various modified collagens are given. In these experiments, portions of the substrate equal to 1·0 gm. of collagen were made to react with 25·0 ml. of the solutions of the chromium perchlorates for 120 hr. The degree of chromium fixation is stated in m.equiv. chromium bound by 1 gm. of the protein. The preparation and properties of the specimens of modified collagen were described in a recent monograph[4].

The results in Table 1 indicate the following facts. By increasing the number of co-ordination sites on the collagen, that is, uncompensated —CO·NH— links, by heat shrinkage (No. 2) and by pretreatment of the hide powder with concentrated solutions of lyotropic agents (No. 7), the fixation of the chromium complexes in the form of neutral compounds is practically doubled, while the fixation of cationic chromium complexes of the 67 per cent acid chromium perchlorate is only slightly affected. This indicates the dominance of the keto-imide groups of collagen in the fixation of uncharged chromium complexes. By the inactivation of the carboxyl groups by methylation (No. 3), the binding of the cationic chromium complexes is practically eliminated, whereas the uncharged complexes of the extremely basic perchlorate still show marked affinity for the modified collagen, the amount of chromium fixed being about 60 per cent of that of intact collagen. By complete acetylation of the ε-amino groups, or by their diazotization, the reactivity of collagen towards the chromium perchlorates is changed very little. In the case of the exhaustively acetylated specimen, with all the ε-amino groups and the major part of the hydroxy groups affected, the fixation of the extremely basic perchlorate is favoured, while that of the cationic chromium complexes is slightly lowered. The markedly increased reactivity of the completely acetylated collagen with the non-ionic chromium complexes is probably due to the freeing of some of the —CO·NH— links from the hydroxy groups of the hydroxyproline residue, making additional sites available for hydrogen-bonding[5].

In specimen No. 8, with practically complete blocking of the —CO·NH— links and a partial inhibition of the reactivity of the ionic protein groups, the uptake of uncharged chromium complexes is practically prevented, while the cationic chromium complexes still show great affinity for the tanned collagen. The lowered fixation is, in the latter instance, probably to be accounted for by the impaired reactivity of the ionic groups of collagen resulting from its binding of tannic acid[2]. All these findings are in harmony with the supposition that the uncharged (non-ionic) chromium complexes of the 33 per cent acid perchlorate are reacting with and attached to the keto-imide groups of collagen. Final proof is provided by the large fixation of the chromium complexes by the modified polyamide, which fixes about 75 per cent of the amount of chromium bound by intact collagen from the 33 per cent acid chromium perchlorate. The polyamide is inert to cationic chromium complexes which require ionic carboxyl groups for their fixation. Its reactivity is limited to the —CO·NH— link.

Hydrothermal stability. As a measure of the degree of effectiveness of the two types of chromium complexes in stabilizing collagen, the determination of the temperature of shrinkage, T_S, is a simple but very informative indicator. Specimens of isoelectric calf-skin, which had been tanned with the 33 per cent acid chromium perchlorate to contain 3·1 m.equiv. chromium per gm. of collagen, commenced to shrink in water of 84–86° C. Specimens which had been tanned with the 67 per cent acid chromium perchlorate to contain 2·0 m.equiv. chromium per gm. of collagen shrunk at 92–94° C. It should be noted that by the binding of about 2 m.equiv. chromium per gm. of collagen in the form of cationic sulphato-chromium complexes, complete resistance of the chromed collagen to boiling water is obtained ($T_S >$ 100° C.). In this connexion, it is of interest and of some significance to note that by fixation of vegetable tannins, that is, polyphenols which are hydrogen-bonded to the keto-imide groups at several points, the shrinkage temperature of skin collagen is increased to 80–90° C. by the most effective tannins[2]. The degree of stabilization of collagen obtained in the two processes, the vegetable and this non-ionic mineral tannage, involving mainly —CO·NH— links, is evidently of the same order of magnitude.

Reaction with gelatin solution. Gelatin is the classical reagent for vegetable tannins, already studied by Davy[6]. In slightly acid solution (pH 3–4), gelatin forms a copious precipitate with solutions of tannins. Since urea-formaldehyde condensation products, which contain the —CO·NH— link as the chief functional group, are equally effective precipitation agents for vegetable tannins as gelatin[7], the reaction is generally believed to be an attachment at several points of the polyphenol to the —CO·NH— links of adjacent gelatin molecules, resulting in the formation of insoluble aggregates[8]. Cationic chromium complexes do not show this reaction. However, by adding a solution of the 33 per cent acid perchlorate to the gelatin solution, a bulky precipitate was formed. It was filtered off immediately, washed and analysed for chromium, perchlorate and protein (nitrogen × 5·56). The filtrate was also analysed. The results are given in Table 2.

Table 2. PRECIPITATION OF GELATIN SOLUTION BY SOLUTION OF 33 PER CENT ACID CHROMIUM-PERCHLORATE

Reaction balance :	Chromium (m.equiv.)	Perchlorate (m.equiv.)	Per cent acidity
Original solution	10·00	3·30	33
Residual solution	4·10	2·24	55
Fixed by the gelatin	5·90	1·06	18
Fixed by 1 gm. of protein	*14·8*	*2·65*	*18*

The following technique was used. To a portion of 40·0 ml. of 1·0 per cent gelatin solution (400 mgm. of protein), a quantity of 10·0 ml. of the 33 per cent acid chromium perchlorate, 1·00 equiv. chromium per litre, diluted with 30·0 ml. of water, was gradually added with constant shaking. The gelatin used in the series of Table 2 was a normal type of alkali-processed calf-skin gelatin, with its isoelectric point at pH 5·0.

By direct analysis, it was found that the chromed gelatin contained 21·8 per cent chromium sesquioxide, 58·9 per cent protein and 15·0 per cent perchlorate. The per cent acidity of the fixed chromium salt was 17. 14·6 m.equiv. chromium was fixed per gm. of protein.

The keto-imide link as the binding site. The fixation of vegetable tannins by the polyamide proves that the —CO·NH— link is its main reacting centre. Since the hydrogen atom of the phenolic group is the donor in the hydrogen-bond formed with the keto-imide group, its oxygen atom should be the acceptor. That the hydrogen atom of the —CO·NH— link is not necessary for the reaction is proved by the fact that structures containing the —CO·N= group alone, corresponding to the link formed by condensation of the prolines in the collagen chains, possess marked affinity for polyphenols of the vegetable tannin type. Polyvinylpyrrolidone is such a model substance[9]. A precipitate was also formed when a 2 per cent aqueous solution of polyvinylpyrrolidone was gradually added to a solution of chromium perchlorates with per cent acidities less than 33. This test is an additional indication that the complex formation with the non-ionic chromium is localized to the oxygen atom of the keto-imide group. However, gelatin is by far the most efficient precipitating agent for the uncharged chromium complexes, which might be due to the participation of auxiliary groups of the protein, lacking in the polyamide and polyvinylpyrrolidone.

By the fixation of cationic chromium complexes by collagen, its isoelectric point is shifted towards higher pH values, or from $p\mathrm{H_I}$ 5 to $p\mathrm{H_I}$ 7–7·5[2], due to the partial inactivation of carboxyl ions of the zwitterionic protein. Applying the dye-technique, the pH_I was found to be 5·5 for the chrome-collagen compounds obtained by tanning with the extremely basic perchlorates of chromium. Thus, no appreciable displacement of the original isoelectric point of the collagen occurred due to the non-ionic chrome fixation. The binding of chromium by the non-ionic protein groups should not be expected to affect the location of the pH_I.

The results of the present investigations suggest that the keto-imide group of collagen is responsible for the irreversible binding of the nonionic chromium complex of extremely basic perchlorates of chromium. No definite information on the nature of the valency forces involved in the attachment of the chromium complexes to the —CO·NH— link at several points has as yet been obtained, whether the binding takes place by co-ordination of the oxygen atom of the keto-group on the chromium complexes, the formation of some type of hydrogen bond, or by ionization of the —NH— link, or by a combination of such reactions. Rabin[10] and Murphy and Martell[11] have presented evidence that peptide oxygen rather than peptide nitrogen is involved in the reversible interaction of some metal ions with simple peptides. The findings of improved hydrothermal stability and the changed reactivity of the chromed collagen, as well as the ability of the non-ionic chromium complexes to precipitate gelatin are satisfactorily explained by a reaction involving co-ordination of the chromium atoms on the oxygen atom of the keto-group of the keto-imide link. The main feature, which is firmly established, is that the compounds formed represent a novel type of metal-protein compounds which may be of value for the location of uncompensated keto-imide links in proteins, for example, by modern optical methods.

OBITUARIES

Mr. R. W. Sloley

THE news of the death of Mr. R. W. Sloley, of Amersham, Bucks, on August 19 at the age of seventy-nine, has been received with sorrow by a large circle of friends and scholars. He took his degree at St. John's College, Cambridge, and he never lost contact with his University. After graduating, he joined the staff of Liverpool College, but during the First World War he went to the Department of Instrument Inspection of the Air Ministry, where he remained for the rest of his professional career. He speedily made his mark in this Department, and during the War spent some time stationed in France. When peace came, he continued his work at the Air Ministry depot at Kidbrooke, and during his service there he wrote a book on aircraft instruments which ran into several editions and is still in use.

At first he lived at Blackheath, but in the later 1920's he migrated to Amersham, where, while continuing to serve at Kidbrooke, he settled down for the rest of his life in company with his father and his sister, for he never married. Both these relatives died before him, and during the last years of his life he lived alone except for his books and his many friends, to whom he frequently extended hospitality. Early in 1939 he retired from the Air Ministry, and thereafter devoted himself to his many hobbies.

Sloley was a widely travelled man, and in his earlier years had visited South Africa and India, for he had connexions with both countries. His interests outside his regular work included music and the arts (he became vice-president of the Chiltern Arts Club during his residence in Amersham); also science, general archæology and Egyptology. In this last subject he was particularly interested; he studied the Ancient Egyptian language for a year or two at University College, London, but his real interest was in Egyptian mathematics and science, and more particularly in Egyptian astronomy and methods of measuring time, on which topics he was probably better informed than any English professional Egyptologist. In November 1930 he delivered to the Egypt Exploration Society an admirable lecture on primitive methods of measuring time which was afterwards published in Vol. 17 of *The Journal of Egyptian Archæology*, and in 1942 he contributed the chapter on science to the volume, "The Legacy of Egypt", edited by the late Prof. S. R. K. Glanville. He also served for some years on the committee of the Egypt Exploration Society. He did a great deal of lecturing to schools and societies, and once in the days of 2LO broadcast a talk on "A Day in the Life of an Egyptian Schoolboy". His last contribution to Egyptian archæology was a brief note in Vol. 39 of the *Journal of Egyptian Archæology* on radio-carbon dating as applied to Egyptian antiquities. His interest in ancient science, however, was not confined to Egypt, but extended also to Babylonia, and even perhaps to India. Under his quiet manner lay an unusually wide culture, and he will be greatly missed by all who knew him. R. O. FAULKNER

Prof. George Fegler

AFTER a distinguished career in medical and biological research, George Fegler died in Cambridge on September 23 at the age of fifty-nine. In Poland, between the time that he received his medical degree (Warsaw, 1924) and the outbreak of the Second World War, he held a number of important research and teaching posts, and in 1939 had just been elected to the chair of physiology at Vilna when he was recalled to the Army. Afterwards he worked in Edinburgh, where, during 1941–46, he was professor of physiology in the Polish Medical School and took part in the war research programme of the University

Department of Physiology. In 1950 he was appointed principal scientific officer at the Agricultural Research Council Institute of Animal Physiology, at Babraham, a post which he held until his death.

His thirty-four years of research covered an unusually wide range of problems; but his greatest interest was in respiratory and cardiovascular physiology, and it was in connexion with problems in these fields that he had recently developed his thermodilution method for the measurement of blood-flow. The method is similar in principle to other indicator–dilution methods, notably the dye–dilution technique, but for certain purposes has a number of advantages over that method. Fegler himself used it successfully to determine cardiac output, renal and portal flow in the dog and sheep; other laboratories had shown considerable interest in the method and had requested his assistance in modifying it for other uses, notably as an aid to clinical investigation.

The method, while favourably received by some, was criticized by others, chiefly on theoretical grounds. Fegler met criticism by testing experimentally each point that had been raised, and extending his controls so that he could assert with confidence that the method fell within the same limits of error as other accepted methods. He also presented a reasoned analysis of the thermodilution curves which showed that perhaps his critics rather than he had strayed into error. But he took no pleasure in polemics. He examined all criticism carefully so as to be sure he had a reliable tool for the research which he had planned. Some progress in this work, a study of the normal shifts in blood-flow from different organs in relation to the metabolic demands of the body, had already been made by him. It is typical, however, that he was at the same time attempting to improve his methods, so that he could, on one hand, achieve more nearly physiological conditions of experiment, and on the other, come closer to that impossible goal of physiologists, an ideal method of measuring blood-flow.

To his colleagues, with whom he discussed these and other problems and who have in the past benefited so much from his experience and scientific knowledge, his loss is a very real one. CATHERINE O. HEBB

Mr. C. C. Mason, O.B.E.

MR. CECIL CHARLES MASON died suddenly on September 9 at the age of seventy-seven.

Mr. Mason graduated with a first in the Mathematical Tripos at Cambridge, and joined the Cambridge Instrument Co. in 1910. He was a joint managing director from that year until his retirement from executive work in 1941, and he remained on the Board until his death. Appointed O.B.E. for his work on shell fuses in the First World War, Mr. Mason was not only responsible for many other technical advances in the instrument field, but also made major contributions to the Company's growth through his wise administration and financial acumen.

Mr. Mason was respected by everyone, and his loss will be keenly felt by a host of friends.

NEWS and VIEWS

Atomic Energy Research Establishment, Winfrith Heath: Mr. D. W. Fry

IN 1956 the Atomic Energy Authority decided to build a new establishment of its Research Group. A site was chosen at Winfrith Heath in Dorset, and, after a public inquiry, the Authority was given permission to use it in 1957. Work is advancing rapidly on this new establishment, and the Authority has announced the appointment of Mr. D. W. Fry as the person responsible to the director of the Research Group for its development and the initiation of the programme.

Donald William Fry, who was born at Weymouth in 1910, was educated at Weymouth Grammar School and King's College, London. He worked in the General Electric Company's research laboratories for four years before moving to the Royal Aircraft Establishment, Farnborough, in 1936. There he took part in the development of very high-frequency communication equipment for R.A.F. Fighter Command. During 1940–45 he served in the Telecommunications Research Establishment on the development of microwave radar. Fry, and several of his colleagues, joined the staff of the Atomic Energy Research Establishment in 1946. This group, working in Malvern, demonstrated the practicability of the high-current linear accelerator and the electron synchrotron. Fry was awarded the Duddell Medal of the Physical Society in 1950. He became head of the General Physics Division at Harwell in 1950. The main work of the Division has been in the high-energy accelerator and thermonuclear fields. Fry was appointed chief physicist of the Atomic Energy Research Establishment in August 1954 and promoted to be a deputy director of the Establishment in February 1958.

Atomic Energy Research Establishment, Harwell

THE following staff changes at the Atomic Energy Research Establishment, Harwell, are announced by the United Kingdom Atomic Energy Authority:

Dr. J. V. Dunworth, formerly head of the Reactor Division, has been appointed assistant director (reactor research policy). In this post he will be special adviser to the director of Harwell. He is succeeded as head of the Reactor Division by Mr. T. M. Fry, who has been a deputy head of the Reactor Division.

Dr. Peter Thonemann, head of the Controlled Thermonuclear Reaction (Fusion) Division at Harwell, has been granted study leave for one year from March 1959. He will be going to the Institute of Advanced Studies in the University of Princeton, where he will work on plasma physics. In Dr. Thonemann's absence the Harwell fusion programme will be carried forward by his deputy, Mr. R. S. Pease, under the supervision of Mr. D. W. Fry, who is deputy director of Harwell with special responsibility for this work (see also preceding note). Dr. Thonemann will be available for consultation.

Physiology at the Medical College of St. Bartholomew's Hospital: Prof. K. J. Franklin, F.R.S.

THE news of Prof. K. J. Franklin's retirement from the chair of physiology at St. Bartholomew's Hospital has been received with much regret by his many friends and former pupils. Franklin went to Oxford after service in the First World War. He obtained a first-class degree in the Final Honours School of Physiology, studied medicine at St. Bartholomew's Hospital and returned to Oxford as a Fellow of Oriel College in 1924. He was a demonstrator in pharmacology from then until 1935 when he was appointed assistant director of the Nuffield Institute for Medical Research. He was dean of the Oxford Medical School for many years, and went to St. Bartholomew's as professor of physiology in 1947. Prof. Franklin was very interested in the venous side of the cardiovascular system, an interest which led in 1933 to collaboration with Prof. Janker, of Bonn, one of the pioneers of X-ray cinematography. When the Nuffield Institute for Medical Research was established in 1935, special provision was made for the study of X-ray cinematography as applied to medical problems. Within a few years Franklin's foresight was justified by the first experimental demonstration of the course of the fœtal circulation. This work, in collaboration with Dr. A. E. Barclay and Sir Joseph Barcroft, finally settled a controversy which had lasted for nearly two centuries, and also provided the first direct evidence as to the nature of the changes in the circulation after birth. In 1947 the same method applied to the kidney led to the publication of some exciting and controversial "Studies of the Renal Circulation" in collaboration with Trueta, Barclay, Daniel and Prichard. Apart from Prof. Franklin's interest in the venous system (a "Monograph on Veins" was published in 1937, and "Cardiovascular Studies" in 1948), his meticulous researches into the history of physiology and his facsimile editions and translations of early writers on the circulation have earned the gratitude and respect of his colleagues. Within the past two years he has followed these with admirable translations of Harvey's "De Motu Cordis" and "De Circulatione Sanguinis".

Prof. M. de Burgh Daly

PROF. Michael de Burgh Daly, who has been appointed to succeed Prof. K. J. Franklin in the University chair of physiology at St. Bartholomew's Hospital Medical College, is also particularly interested in the control of the circulation and respiration. After taking the B.A. degree in Cambridge in 1944, he proceeded to St. Bartholomew's Hospital and qualified M.B., B.Chir. in 1947. After a house appointment, he joined Prof. G. L. (now Sir Lindor) Brown in the Department of Physiology at University College, London, and began research with the late Alfred Schweitzer. His interests in circulatory and respiratory physiology stem to some extent from the influence of Schweitzer and from that of his distinguished father, Dr. Ivan de Burgh Daly, until recently director of the Institute for Animal Research at Babraham, who has made great contributions to these subjects. Prof. de Burgh Daly spent 1952–53 in Philadelphia as Rockefeller Fellow in Prof. Schmidt's department. On his return he was appointed Locke Research Fellow of the Royal Society. His research activity has been considerable and fruitful. Among a long list of papers, notable have been those on the baroreceptor regulation of cardiac output, on the blood supply and oxygen usage of the carotid body and on chemoreflex responses of the pulmonary circulation.

Botany at Edinburgh: Prof. R. Brown, F.R.S.

THE appointment of Dr. Robert Brown to the regius chair of botany in the University of Edinburgh, in succession to the late Sir William Wright-Smith, can scarcely fail to mark a new chapter in the history of botany in Scotland. The Department of Botany in Edinburgh has a long and honourable tradition of taxonomy, and Dr. Brown has achieved a notable reputation as a plant physiologist with a very individual outlook; his activities in this new sphere will be watched with the liveliest interest. His earlier work includes contributions to the study of the stimulation of germination in seeds of the parasite *Striga* by root exudates from the host; but the bias of his more recent researches has arisen from the development and imaginative exploitation of a powerful new technique for the estimation of cell numbers in growing-points and the tissues immediately behind them. The combination of a maceration technique with a hæmacytometer cell-counting method has made it possible to express the results of chemical and other estimations on a per cell basis. This has given the impetus to a remarkable series of studies of the development of cells from growing-points, carried out by Dr. Brown and his co-workers, first at Leeds and later (from 1953) in his very active Agricultural Research Council Unit of Plant Cell Physiology at Oxford. A brief summary of Dr. Brown's career appeared in *Nature* of October 11 (p. 992).

Pharmaceutical Society of Great Britain

A PORTRAIT of the late Prof. John Attfield, for thirty-four years professor of practical chemistry to the Pharmaceutical Society of Great Britain, was presented to the Society after the October meeting of the Council by his grandson, Mr. C. A. Brooks, of Dedham, Essex. The portrait is a replica of one given to Chicago pharmacists which was painted in recognition of the work done by Prof. Attfield in helping to "raise their College from its ashes after the Great Fire of 1871". With the portrait, Mr. Brooks handed to the Society a complete set of the nineteen editions of his grandfather's famous textbook of pharmaceutical chemistry and an album containing an illuminated address and 1,240 signatures of professional colleagues, including those of Lord Lister, Sir William Crookes and Sir Henry Wellcome. In accepting the gifts, Mr. Hudson, president of the Pharmaceutical Society, said they would be a perpetual reminder of the prominent place Prof. Attfield occupied in the Society's history and in the scientific world; and of the services he had rendered to pharmacy and to medicine. He served the Society from 1862 until 1896. Probably, said Mr. Hudson, Attfield's greatest achievement was his work for the "British Pharmacopœia"; and by the time of his death he had the satisfaction of knowing that it was legally adopted in all British Dominions.

Josiah Wedgwood and Research

IN his 1957 presidential address to the North Staffordshire Field Club, J. Leighton directed attention to letters written by the famous eighteenth century potter, Josiah Wedgwood, to his colleague, and later, partner, Thomas Bentley (*Trans. N. Staff. Field Club*, 91; 1958). The letters show how, in company with other Staffordshire potters, Wedgwood planned so early as 1755–56 a co-operative research establishment for the pottery industry.

Following a patents dispute, proposals were made that a joint stock experimental company be established for the purpose of the general improvement of the manufacturers' products. Among the Wedgwood papers are the committee's "Heads of an Agreement, etc.", the first of which runs: "Proceedings in the scheme of an Experimental Work. The Commee. were of opinion that all who had subscribed to the opposition etc. shod. have a choice of becoming Members of a Company for carrying it into execution, and they were invited by circular letters, in consequence of which, they will meet on Tuesday next, when will be laid before the following Heads of an Agreement to be entered into. . . . We do mutually agree to establish an Experimental work for the purpose of trying the materials lately brought from Cornwall, as well as those which may in future come from that County as any other place in order to improve our present manufacture and make an Useful White Porcelain Body, with a colourless glaze for the same and a blue paint under the glaze. It was also proposed that no member shall disclose the experiments made by this Company or the knowledge obtained by them to any person or persons not in the Company, on pain of forfeiting his share in the joint Stock, and of incurring a penalty of One thousand pounds and that no one of us shall take advantage of the knowledge acquired by the experiments of this Society, by adopting any of the improvements made thereby in our own private manufactories or otherwise, until the plan and time of generally adopting and removing such improvements into the manufactory at large to be agreed upon by the Society under the penalty of One thousand pounds".

Unfortunately the plan came to nothing, but Wedgwood went on to write: "Having done my duty I am contented, and shall take my own course quietly by myself as I can, and may perhaps have it in my power to serve the trade some other way. . . . I shall now begin with the materials in earnest. I scarcely thought myself at liberty to do so whilst the Partnership plan was in agitation".

Historic Aircraft Maintenance Group

A GROUP of volunteers composed of members of the Royal Aeronautical Society and of the Society of Licensed Aircraft Engineers is about to begin work on repairing and maintaining the aircraft of the Nash Collection of historic aircraft now owned by the Royal Aeronautical Society. Since it acquired the Nash Collection in 1954, the Royal Aeronautical Society has had many difficulties in the storing and housing of the aircraft, but recently a hangar at the R.A.F. Station, Hendon, was made available. An appeal for volunteers living in the London area to work on the aircraft, made by the secretary of the Society in July this year, met with an enthusiastic response. Members of the two Societies are now starting work, giving up their week-ends to get these historic aircraft back to display condition. Captain E. D. Ayre, a past president of the Society of Licensed Aircraft Engineers, has been appointed chief engineer of the Historic Aircraft Maintenance Group. He has already undertaken a preliminary inspection of the aircraft and has started to collect the necessary equipment. Captain Ayre will supervise a team of engineers who have had extensive practical experience on the types of aircraft and engines in the Nash Collection. The guiding principles will be preservation rather than renovation, so ensuring that the craftsmanship of an earlier generation is not lost. It is hoped that, ultimately, the Society's Nash Collection will form part of a National Collection of Aircraft.

The Border Country in Britain

THE Forestry Commission's decision to declare the Border Country the eighth national forest park of Great Britain will give pleasure to all who have watched the planting, growth and development of the Forests of Kielder, Wark, Redesdale, Kershope, Newcastleton and Wauchorpe during the past thirty-five years. Their pleasure will be enhanced by the publication of a national forest park guide which worthily maintains the high standards of its predecessors (The Border. Edited by Prof. John Walton. National Forest Park Guides. Pp. vi + 94 + 16 plates. London: H.M. Stationery Office, 1958. 5*s*. net). The bulk of the guide consists of accounts by H. L. Edlin of the land, the people, the poetry and legend of the Border, the Border forests and walks most likely to bring pleasure to nature-lovers. The Border region in Roman times is described by Prof. I. A. Richmond, and the history is continued by Prof. J. D. Mackie. Dr. W. A. Clark discusses the vegetation of the park, and Ernest Blezard the wild-animal life. The geology of the region is examined by Dr. G. A. L. Johnson. An extensive bibliography has been carefully built up by three prominent librarians. There is also the usual and indispensable section called "General Information"—which will help those who are new to the area to find their way about more quickly, profitably and, where appropriate, economically. Splendidly illustrated with verse, black-and-white sketches, photographs and maps, the guide is excellent value at 5*s*. The Forestry Commission and, particularly, Mr. Edlin deserve the highest praise for the quality of these publications.

Recent Phycological Publications

THE attention of readers interested in the problems of the algae may be directed to the *Phycological Bulletin* (No. 6, June 1958, pp. 1–53, issued by the British Phycological Society; *President*, Dr. J. W. G. Lund; *Hon. Editor*, Dr. Elsie Conway, Department of Botany, University of Glasgow). This issue gives a clear indication of the officers, construction and aims of the Society, namely, to pursue the scientific study of marine and freshwater algae on the widest basis. The contents include tributes to the late Dr. Kathleen M. Drew, who did so much to further the study of these organisms and to found the Society, abstracts of papers read at the London meeting in January 1958, and a variety of topics of both general and special interest to algologists. In particular, reference should be made to important tables of chromosome numbers in the Ulotrichales and in the brown algae, the authorship being cited in each instance. A volume of abstracts of the third International Seaweed Symposium, held in Galway, Eire, in August 1958, has also come to hand (pp. 1–82; University College, Galway). Some seventy-one papers, covering a very wide field, were submitted. These include such topics as biophysical and biochemical aspects of some algae, the possibilities of the mass culture of microscopic marine algae, their utilization as sources of raw materials, cytological and ecological studies, and so on. Yet a further contribution to algology comes from the Nova Scotia Research Foundation. This consists of a "Selected Bibliography on Algae" (No. 4. Pp. 1–109. Halifax, Nova Scotia), and includes references to chemical and physical studies, culture, ecology, physiology, biology, morphology, taxonomy and utilization.

The World Health Organization

"An International Nomenclature of Yaws Lesions", by Dr. C. J. Hackett, in co-operation with an international group of experts and participants of the international conference on yaws control held at Enugu, Nigeria, in 1955 (World Health Organization Monograph Series No. 36. Pp. 103. Geneva: World Health Organization; London: H.M. Stationery Office, 1957. 12 Swiss francs; 20*s.*; 5 dollars), is an outstanding contribution to the study of the disease called, in English, 'yaws', in French 'pian', in German and Dutch 'frambœsia', in Spanish 'buba', and in Portuguese 'bouba'. The various names used in the study of the disease are defined, and the stages in the disease are described. There are seventy-six plates showing the frightful lesions caused by the spirochæte, *Treponema pertenue*, which is responsible for the disease. Some of these show the remarkable healing without scarring that may follow a single injection of penicillin. The nomenclature supersedes the earlier one given in the World Health Organization Monograph Series No. 5, entitled "Atlas of Frambœsia", by K. R. Hill, R. Kodijat and M. Sardadi, published in 1951. The successful reduction of yaws and the campaigns against it sponsored by the Organization and by UNICEF are described in "The First Ten Years of the World Health Organization" (pp. viii + 540 + 28 pages of photographs. Geneva: World Health Organization; London: H.M. Stationery Office, 1958. 25*s.*; 5 dollars; 15 Swiss francs), which gives a comprehensive survey of its achievements in the many fields of health control and eradication of disease in which it operates all over the world. Another account of its achievements, illustrated by remarkable photographs of the work actually in progress, and attractively written by Ritchie Calder, is entitled "Ten Steps Forward, World Health 1948–58" (London: H.M. Stationery Office, 1958. 2*s.* 6*d.*).

Health in the Tropics

The report of the thirty-second meeting of the Ross Institute Industrial Advisory Committee on June 19 (pp. 19. London: London School of Hygiene and Tropical Medicine, incorporating the Ross Institute, 1958) records the address given by Dr. Alan Gilroy, principal of the India Branch of the Institute, and the subsequent discussion. Dr. Gilroy referred to the progress made in regard to malaria. In a large sample of tea-estate labour there were 12 cases of malaria per 1,000 in 1957, no deaths, and a spleen rate of only 1·5 per cent. As a result, with the adoption of a malaria-eradication programme by the Government of India, the industry could now contemplate relief from its recurring expenditure of nearly thirty years. Anæmia remained a most important cause of ill-health, and about 90 per cent of the cases are of simple iron-deficiency anæmia, although the diet was not short of iron and patients were not losing it to hookworm. In replying in the discussion, Dr. Gilroy said that the scientific investigation of malnutrition was as yet incomplete, but it appeared that although the diet was adequate in quantity it was deficient in quality. This was due to ignorance rather than to lack of purchasing power. Dr. Gilroy also said that the stage had been reached when it was accepted and recognized that family planning was necessary, and he also referred to the lecture courses in tropical hygiene for planters and the refresher courses held for tea-estate assistant medical officers.

City and Guilds of London Institute

The rapid growth of technical education in Great Britain and overseas is well brought out in the seventy-eighth annual report of the City and Guilds of London Institute, for the year October 1, 1956, to September 30, 1957 (Pp. v + 118. London: City and Guilds of London Institute, Gresham College, 1958). In 1957, 119,948 students took one of the great variety of courses arranged by the Institute compared with 105,815 in 1956; it is not surprising to learn that 62·5 per cent of students in Great Britain and Ireland were successful in their examinations, whereas the number of successful overseas students was 48·1 per cent. Of the students, almost half of them (54,391) took courses in electrical subjects, 21,715 courses in mechanical engineering, 18,640 in building subjects, and 9,378 in chemistry subjects. Other courses taken were in domestic subjects, printing and food technology. Many of the courses were revised during the year and a number of new ones were added; among the latter is a course for a National Certificate in Agriculture for students who have completed a year at a farm institute. The report also contains details of the insignia awards in technology, the work of the art school and the City and Guilds College, as well as the response to examinations set by the Associated Examining Board for the General Certificate of Education.

The Cosmic Distance Scale

In his Warner Lecture before the American Astronomical Society, Dr. Allan Sandage has reviewed the current status of work on the cosmic distance scale (*Astrophysical Journal*, 127, 513; 1958; *Sky and Telescope*, 17, 275; 1958). Hubble's criteria for setting up the distance scale have been re-examined. He used the brightness of the cepheid variable stars in the Andromeda and Triangulum nebulæ, the brightness of individual high-luminosity stars for somewhat more distant galaxies, and integrated apparent magnitudes of still more distant objects. The first criterion was revised in 1952 when Baade showed that classical cepheids were 1·5 magnitudes brighter than had been supposed: this effectively doubled the scale of distances. Other complicating features have since been discovered: the period-luminosity 'curve' seems to be a broad band, and new methods will have to be devised to find out whether individual cepheid variables are under- or over-luminous for their periods. One can therefore scarcely rely on the cepheid criterion for the thirty galaxies in which these stars can be seen with the 200-in. telescope.

Sandage has shown that Hubble's second criterion was incorrectly applied, in that many of the objects which Hubble believed to be bright stars were in fact ionized hydrogen regions; their nature only became evident when photographs were obtained through Hα filters. In the nebula M 100, for example, objects at magnitude 19·0 are ionized hydrogen regions, not stars, the brightest stars appearing at magnitude 20·8. If these individual stars have absolute magnitudes of − 8·5, the distance of M 100 would be about six times its value on the 1936 distance scale; the Hubble constant of recession would be 87 km./sec./megaparsec. A similar result follows from studies of the globular clusters in the nebula *M* 87. These arguments do not constitute a rediscussion of the distance scale. Precise new measurements are required for this, and such measurements are now in progress at Mount Palomar.

Atoms for Peace Conference: American Publication

AT the second International Conference on the Peaceful Uses of Atomic Energy recently held in Geneva, a set of twelve volumes dealing with the American participation, written expressly for the Conference and containing much information just declassified, was presented to official delegates as a gift from the United States. These volumes have now been published by Addison-Wesley Publishing Co., Inc., Reading, Mass., on behalf of the U.S. Atomic Energy Commission. (The volumes are also obtainable from Academic Books, Ltd., 129, Queensway, London, W.2.) The price of each separate volume varies from 45*s*. 6*d*. to 92*s*.; but the complete set is available at £30. Further information can be obtained from either the Addison-Wesley Publishing Co., Inc., or Academic Books, Ltd., at the above addresses.

Mammal Society of the British Isles

A SYMPOSIUM entitled "Mammals in British History and Prehistory" will be held in the meeting room of the Zoological Society of London, Regent's Park, on November 1. Non-members of the Society are invited to attend; there is no registration fee. The programme will include talks on the conditions for the preservation of mammalian remains, and blood grouping of human remains; the mammalian fauna and environmental conditions at the close of the Pleistocene; the mammalian fauna from Star Carr; and the historical development of farm animals in relation to their environment. Further details can be obtained from the conference secretary, Dr. K. M. Backhouse, Charing Cross Hospital Medical School, 62–65 Chandos Place, London, W.C.2.

Torry Research Station

THE Council for Scientific and Industrial Research announces that responsibility for the research programme of the Torry Research Station at Aberdeen will be vested in a steering committee, consisting of: Dr. B. K. Blount (*chairman*), deputy secretary of the Department of Scientific and Industrial Research; Mr. G. C. Wilson, a member of the White Fish Authority and the Herring Industry Board; Dr. D. Traill, director of research of the Nobel Division of Imperial Chemical Industries at Stevenston, Ayrshire; Mr. H. Wooldridge, head of the Stations Division of Headquarters, Department of Scientific and Industrial Research; and the director of the Station, Dr. G. A. Reay. Dr. Reay's title was formerly 'superintendent', but it has now been changed to 'director'.

Announcements

MR. J. WILSON has been awarded the Hinchley Medal of the British Association of Chemists for 1957. The formal presentation will be made at the Royal Society of Medicine (West Hall), 1 Wimpole Street, London, W.1, on October 29, at 7 p.m. Mr. Wilson will then deliver the Hinchley Memorial Address, which is entitled "Grant-aided Research Associations".

MR. ALEC M. HUGHES, general secretary of the Scientific Film Association, has been appointed visual aids officer of the British Association for the Advancement of Science.

MR. A. P. GAGNEBIN, who has been elected a vice-president of the International Nickel Company, Inc., joined the Company's research laboratory at Bayonne, New Jersey, in 1932 and devoted himself to research on ferrous metals. He became a member of the Ductile Iron Section of the International Nickel Company's Development and Research Division in 1949, where he was active in the industrial development of ductile iron, of which he is a co-inventor. In May 1952, Mr. Gagnebin was a co-recipient of the Peter L. Simpson Gold Medal of the American Foundrymen's Society, for outstanding work and development in the field of ductile iron. He is the author of many technical papers and of the book, "The Fundamentals of Iron and Steel Castings".

THE British Council (65 Davies Street, London, W.1; telephone, Grosvenor 8011) asks senior academic scientists who are contemplating overseas tours (other than to the United States) to inform it of their intentions. The Council can often help with specialist contacts—and can sometimes arrange lectures by the traveller—in the countries to be visited or *en route*. Such collaboration is greatly valued by the Council as an important contribution to its efforts to promote a wider knowledge overseas of the sciences in Britain. Communications on this subject can be addressed to the Director, Specialist Tours Department.

THE winter conference of the Physical Society, on physics of the solid state, will be held in the Cavendish Laboratory, Cambridge, during December 18–20. The subject of the conference will be interfacial phenomena, and it is hoped that papers will be given on some or all of the following subjects: (1) structure of vacuum-evaporated layers on single-crystal substrates; (2) structure of electrodeposited layers; (3) epitaxy; orientation of crystals on various substrates; (4) grain boundary phenomena; the interface between different phases in metals; (5) the interface between solid and liquid phases. Those wishing to take part are invited to write to Prof. N. F. Mott, Cavendish Laboratory, Cambridge.

THE fourth Congress on Theoretical and Applied Mechanics will be held under the presidentship of Dr. S. R. Sen Gupta at the Bengal Engineering College, Howrah, Calcutta, during December 28–31. Research papers may be contributed on any of the following topics: (1) elasticity, plasticity, rheology; (2) fluid mechanics (aerodynamics, hydrodynamics); (3) mechanics of solids (ballistics, vibrations, friction-lubrication); (4) statistical mechanics, thermodynamics, heat transfer; (5) mathematics of physics and mechanics; and (6) experimental techniques. Registration forms and further information can be obtained from the Secretary-Treasurer, Indian Society of Theoretical and Applied Mechanics, Indian Institute of Technology, Kahragpur, India.

ERRATUM. Reference was made in the article entitled "Academic and Professional Mobility" in *Nature* of August 16, p. 413, to a paper by Dr. P. E. Weatherley; we regret that his name was wrongly spelled in that article and also in an earlier article (*Nature*, 181, 677; 1958).

ATMOSPHERIC DIFFUSION AND AIR POLLUTION

AN international symposium on "Atmospheric Diffusion and Air Pollution", arranged jointly by the International Union of Theoretical and Applied Mechanics and the International Union of Geodesy and Geophysics, was held in Oxford during August 24–29. The symposium brought together from various countries nearly one hundred scientists, mainly meteorologists and fluid dynamicists, with active interests in one aspect or another of the physics of turbulent diffusion. The scientific programme was planned by a committee under the chairmanship of Sir Geoffrey Taylor and the joint secretaryship of Dr. F. N. Frenkiel (Johns Hopkins University) and Prof. P. A. Sheppard (Imperial College of Science and Technology, London), and was expressly designed to examine outstanding basic problems in the study of atmospheric diffusion and its application to air pollution studies. Accordingly, after an opening session which included broad surveys of the distribution and effects of the airborne products of combustion, conventional industrial processes and nuclear processes, the proceedings were organized into sessions dealing with specific aspects of the problem of diffusion. These included the structure of atmospheric turbulence, the theoretical treatment of the diffusion of particles in a turbulent atmosphere, the processes of vertical transfer on all scales in the atmosphere and the effect of thermal stratification thereon, and the distribution of airborne material from artificial sources.

As nearly forty papers were presented, this article would be little more than a catalogue if all were to be mentioned individually. For such detail the reader will shortly be able to turn elsewhere, for the entire proceedings of the symposium, both papers and discussions, are to be published in book form by Academic Press, Ltd., and it is hoped that they will appear before the end of the year. The aim of this article is rather to comment on some of the major issues brought out in the proceedings.

The scientific treatment of atmospheric diffusion was effectively started by Sir Geoffrey Taylor in 1915 in his classical work on the vertical transfer of heat and momentum by eddies in the atmosphere. This work was the beginning of one of the two main approaches to the subject, the approach which is concerned with the 'bulk' properties of the fluid, especially the gradients of the mean properties undergoing diffusion, as distinct from the other main approach involving preoccupation with the internal structure of the fluid. The real beginning of this latter approach was also provided by Taylor, in 1921, in a paper in which diffusion was related to the correlation between the eddy velocities of a given element of fluid at specified times. Then in 1926 L. F. Richardson put forward a novel theory of atmospheric diffusion which implicitly recognized the existence and importance of a whole spectrum of eddy sizes in turbulent motion. More explicit use of the idea of a spectrum came later, at first in a purely formal sense, in the general theory of the statistical mechanics of isotropic turbulence, initiated by Taylor in 1935 and followed up more recently by G. K. Batchelor and others. From a physical point of view, an important step in the development of the concept came with A. N. Kolmogoroff's set of simplifying hypotheses concerning the transfer of turbulent energy from large eddies to small eddies. Although these ideas were put forward in 1941, owing to the Second World War they did not begin to be widely known until nearly ten years later. The fundamental ideas involved in these earlier advances still dominate the background against which the Oxford discussions were conducted.

The contributions on the structure of atmospheric turbulence all indicated the tendency, which has grown rapidly, especially over the past five years or so, to represent this turbulence on the statistical basis which has been so highly developed in the study of wind-tunnel turbulence. Owing to the large range of eddy sizes normally present in the atmosphere, the emphasis has naturally been more on the spectrum of eddy energy than on the time- or space-correlations of the velocity fluctuations, though in practice the time-correlations (from velocity observations at a fixed point) are obtained as an essential intermediate step. The 'power-spectra' derived from them by Fourier transform techniques give the intensities of the contributions, to the total variance of the velocity component, from oscillations of particular frequencies which are contained in the time-variation of the component. These 'time-spectra' are strictly to be distinguished from the so-called Eulerian 'space-spectra', which are correspondingly derived from simultaneous velocity measurements at many fixed points, and which contain a more satisfactory physical representation of the eddy 'size'. However, it has been customary for some time to assume equivalence of the more easily obtained 'time-spectra' with space-spectra in the direction of the mean motion, and evidence on this continues to accumulate.

Two features which were brought out concerning the shape of the spectrum are especially worthy of mention here. If the spectra for the vertical component at heights varying from one to a few hundred metres are 'normalized', by plotting the product of the equivalent wave-number (the reciprocal of the wave-length) and the spectral intensity against the product of the wave-number and the height, there appears to be a general similarity in shape, with a maximum intensity at a wave-length of the order of three times the height above ground. The other features concern behaviour at higher frequencies, where, according to the ideas put forward by Kolmogoroff, all forms of turbulence should exhibit isotropic properties, that is to say, properties which are unaffected by rotation of the axes of reference. The data now accumulating leave no doubt that the limiting eddy size, below which the isotropic structure exists, increases with increasing height above ground, and recent measurements confirm an earlier suggestion that the isotropic limit occurs at an equivalent wave-length approximately equal to the height. Both of these generalizations may well require some qualification when appreciable thermal stratification of the atmosphere is involved, but they represent useful first steps in the provision of an integrated description of atmospheric turbulence.

In the papers relevant to the vertical transfer of momentum and heat in the lower atmosphere, it was encouraging to see the Navier–Stokes equations of fluid motion being used as a starting point for understanding some of the stages in the complex cycle of energy exchange in stabilized and unstable flow. On the other hand, it was evident that some confusion still exists in the empirical description of the effects of thermal stratification. All seems reasonably straightforward so long as the atmosphere is in neutral or near-neutral equilibrium, when the adoption of the familiar universal wind profile (wind velocity varying with the logarithm of the height) enables the flux of momentum (and of other properties) to be usefully estimated merely from measurements of the vertical gradients of wind velocity and of the properties concerned. The long-required extension of this sort of treatment to the cases when the atmosphere is heated or cooled from below has recently seemed to be forthcoming from dimensional analysis. These treatments certainly lead to wind profiles of the required shape in stable and unstable conditions, and also to the correct qualitative variation of vertical flux with degree of stability, but at this point the consistency appears to end. In the first place, there are important differences, which have yet to be explained, in independent measurements of the vertical transfer of momentum near the ground. Furthermore, it seems that the magnitudes of the dimensionless parameters required by the form of the wind profile are of a different order from those required to explain the absolute magnitude of the vertical flux. Since one of the practical interests lies in being able to estimate flux quantities from profile measurements, these discrepancies are frustrating as well as puzzling, and their resolution would represent an advance of some practical importance.

It may be that the resolution of these difficulties will only come as a result of closer attention to the structural properties, as in one of the contributions, where for two specific cases with unstable conditions it was demonstrated that the vertical motions responsible for heat transfer were of larger scale than those responsible for momentum transfer. Moreover, from a number of points there are reminders that with increasing instability and with increasing height above the surface boundary the dominant character of the vertical motion changes from that of mechanically generated turbulence to the more organized motions of thermal convection. Some progress has already been achieved in the representation of the heat transfer by these organized motions, but a useful statistical derivation of the transfer of momentum and other properties has evidently yet to emerge.

In the theoretical treatment of the distribution of particles released in a turbulent fluid increasing use is now being made of the mathematical and statistical techniques which were evolved largely in relation to aerodynamic problems. Many of the developments are still in a highly formalized stage, and the progress made towards rigorous solutions which can be expressed in terms of measurable properties of the turbulence is not immediately obvious. However, one real improvement is to be noted in the more detailed attention which is being paid to the significance of the finite time involved in observing diffusion phenomena. The need for this attention arises directly from the 'width' of the turbulence spectrum, and becomes the more pressing in the case of atmospheric flow, where for many problems the spectrum extends effectively indefinitely into the region of long wave-lengths. Another welcome sign is the increasing recognition of the distinction between the distribution of particles relative to fixed axes after continuous release from a fixed point, and the relative spread of particles released instantaneously in a cluster. These ideas are being adopted to an encouraging degree in a 'model' treatment of the statistical properties of the continuous plume from a fixed source of particles. The accumulation of satisfactory observations on the relative spread of particles is now an outstanding requirement.

Despite these more advanced exploitations of the statistical theories of turbulence, a central problem still remains in the interpretation of the Lagrangian variations of the motion, that is to say, the variations in the velocity of a particle in contrast to the variations which may easily be observed at fixed points in the fluid. This problem was presented from the beginning in Taylor's 1921 analysis, by which the diffusion from a serial release of particles is specified in terms of the Lagrangian correlation coefficient, namely, that between the velocities of a particle at successive instants of time. The gap between this virtually unmeasurable property and the measurable time or space correlations at fixed points has yet to be bridged, and the fluid dynamicists are not yet able to offer any hope of this being achieved soon in the circumstances of concern to the meteorologist.

In the absence of a tractable analytical relation between these Lagrangian and Eulerian properties the realization of the practical end-point in the present subject, that is, the formation of realistic estimates of the distribution of airborne material released in a specified fashion, continues to lean heavily on empirical devices or careful limitation of the physical conditions involved. The latter recourse seems to be used with promising effect in contributions to the diffusion of falling particles with terminal velocities of a limited range, large enough to ensure that Eulerian variations are dominant over Lagrangian variations, yet small enough to exclude serious inertial effects on the response of the particles to the turbulent fluctuations. For floating particles some immediate progress is provided by the empirical step of assuming a simple relation between the Lagrangian correlation function and the auto-correlation function measurable at a fixed point. This has led to a method of obtaining the spread from a continuous point source directly and simply from measurements of velocity fluctuations.

The attainment of rational, albeit empirical, formulæ and methods for predicting diffusion is still mainly confined to the small-scale processes involved in diffusion over a few hundred metres. On the largest scale, involving exchange within and between the troposphere and stratosphere, the position is still one of gaining experience from the behaviour of natural and man-made tracer elements. Much interesting information is accumulating from measurements of fall-out from nuclear tests, and some of this is thought to fit in with current ideas of stratospheric motion based on studies of water vapour and ozone. Another promising radioactive tracer has been recognized in the isotopes produced by cosmic radiation. These have the advantage of being produced practically independently of time and without seasonal or diurnal changes. For the intermediate scale of diffusion, the sort involved in the travel of radioactive material from the Windscale reactor accident in October 1957, little progress has been reported. On this scale, involving heights of several thousands of feet and distances of tens of miles, the processes of dispersal are further complicated on one hand by the variation of the mean wind field with height, and on the ot large-scale effects of thermal stra alternatively to the virtually compl vertical spread or to rapid ascent vective motion. From a practical to this scale of processes that urgently required.

FUTURE OF MINERAL EXPLORATION IN GREAT BR AND IRELAND

THE fourth Sir Julius Wernher Memorial Lecture of the Institution of Mining and Metallurgy was given by Mr. Anton Gray, mining adviser to the U.K. Atomic Energy Authority, at the Royal Institution on September 22, his subject being "The Future of Mineral Exploration". In a survey of the world situation, Mr. Gray maintained that whereas it is unlikely that the present rapid rate of increase of consumption of metals can be maintained, it would not be surprising if the demand for the major metals doubles before the end of the present century. About the beginning of this century the geologist began to take over the work of the prospector, for by then most of the mineral deposits not concealed by younger formations had been found. But he has not had the same success in the search for a method of predicting the occurrence of ore-bodies as his colleague in the petroleum industry has had in finding concealed oil-pools.

This results from his inadequate knowledge of the precise mode of origin of mineral concentrations; for while it is generally agreed that most important ore-bodies were introduced into openings in pre-existing rocks by warm waters, there is no agreement as to the source of the water or of the contained metals. The dominant hypothesis, that of hydrothermal solutions related to granite, had been shown, in Mr. Gray's view, to be adequate only for a limited group of metals, including tin, tungsten, beryllium and some gold concentrations. He suggested an unorthodox but not heretical alternative for the other metals: that the waters are generated during metamorphism associated with mountain-building, and he based this suggestion on two of the great ore deposits of the world, the central African copper belt and the Witwatersrand goldfield. The great part which Mr. Gray has played in mineral exploration in central Africa lends authority to his advocacy of this hypothesis of what might be called metamorphic lateral secretion.

This lecture formed a prelude to a symposium on "The Future of Non-Ferrous Mining in Great Britain and Ireland", held at the Federation of British Industries on September 23–24. The symposium consisted of twenty-four papers, in three broad groups: a series of seventeen devoted to descriptions of the geology, mining history and potentialities of the mineralized districts of Ireland, Scotland, England and Wales; a group of short contributions on technical aids to mineral exploration, such as the various geophysical methods, the use of geochemical prospecting techniques and of air photography; and a series on economics and finance.

The foundation for an approac problems of the mineral fields w past century by the official prima Survey of Great Britain and Irel decline of the tin, copper and lea little further interest in the subj The Special Reports on Mineral Geological Survey, chiefly based on the First World War, brought toget data, but it is probably fair to s investigation by modern methods to the past two decades. The group gave a fair conspectus o reached. As is well known, the m British Isles occur in granite and a Carboniferous slate in the south-w England; and elsewhere chiefly in ments, the Lower Palæozoic slates metamorphics; and the unmeta Carboniferous rocks, chiefly of lime facies. A stratigraphical control– strict relationship between partic logies and introduced mineral bo by W. J. Hughes in central Wale in north Wales, and by H. G. Di shire, in all these cases in Lower but in other districts where the r age, such as the Lake District Leadhills–Wanlockhead (R. A. control has been found. Thus, w though steeply inclined, tend to be where they are related to the st they are not—as, for example, in or Coniston copper mines—the tw tend to be roughly equal. In the of the Pennines and Flint–Denbi well-marked relation to brittle b stone and limestone, as well as to wallrocks such as limestone and influence of impermeable or sem or rotted lavas overlying favour portant in localizing ore-bodies. these districts, as well as in man fields, ore-bodies occur which fail of these have been found by unde but nearly all districts contain prospecting for concealed mineral them of substantial promise. Th for the view that British metalli far from exhausted.

A second line of geological ap of the spatial distribution of individual districts. The zonal is well known and has been clarified by Dines, as well as in K. F. G. Hosking and J. H. Trounson's contribution to the symposium. Zoning has been demonstrated in the northern and southern Pennines by the present writer, broadly corresponding with the outer zones of Cornwall, but lateral rather than vertical in effect. It can be discerned in individual deposits like Bridford, Devon, described by P. G. L. Vipan, in a downward change from barite to sulphides, and Archer notes a broad though probably not genetic zoning in north Wales.

Most important of all, the localization of introduced mineral deposits is controlled by structural features, particularly by fractures which resulted from successive periods of stress and which form a definite pattern in each field; but also by granite cupolas, by folds of various dimensions and even by pre-ore dykes. At Leadhills–Wanlockhead a thrust plane is recognized as the operative control by Mackay. Displacement of ore-bodies by faulting after emplacement also occurred in many districts; in the northern Pennines this may have thickened some oreshoots locally. For Derbyshire it was suggested by W. W. Varvill that definite belts of rich mineralization, oblique to the superficial structure, could be recognized; perhaps these are related to trends in the concealed basement rocks.

Though more detailed structural information is desired in every district, the chief obstacle to successful prediction is present ignorance of the origin of the mineralizing fluids and their paths of ascent. A clear genetic relation to granite is demonstrable only in the south-west of England, and here it is interesting to note that Hosking's interpretation of the form of the granite batholith in depth, based on the distribution of mineral veins, corresponds remarkably closely with the quite independent interpretation based on gravity survey recently presented to the Royal Society by M. H. P. Bott, A. A. Day and D. Masson-Smith. There is evidence of concealed granites beneath the northern Pennines from the gravitational data of Bott and Masson-Smith, but the connexion with mineralization remains to be proved by deep boring. In many other districts, no hint has so far been found of such a connexion. There is, however, evidence from boring that mineralization persists to much greater depths than mining has so far reached, for example at Halkyn, described by G. A. Schnellmann, and east of the north Derbyshire district.

The geological age of the deposits has little bearing on their future value, but it is to be noted that on this aspect some new evidence was forthcoming. A. Fowler showed that the Conlig lead vein near Belfast follows a dolerite dyke of probable Tertiary age; while conversely Archer found that a dyke of the same age cuts through a lead lode at Parc in the Conway valley.

The mineral deposits of the Republic of Ireland, described by M. V. O'Brien, include at Avoca a deposit in Lower Palæozoic slates which has been developed with success in recent years, and which promises to be a major source of copper ore and pyrite. This work, financed by the Government and leading to the revival of a dead industry, exercised a considerable influence upon the discussions at the symposium. The small non-ferrous mining industry in the United Kingdom could be expanded if, using the geological basis which is now becoming available, techniques such as electromagnetic and shallow seismic survey, and geochemical soil sampling, were followed up by vigorous boring programmes. J. S. Webb's work at Gregory in Derbyshire showed how a lead deposit, deeply concealed under shale and grit, yet betrayed its presence by a leakage-dispersion at surface. The hope for the future is in the 'concealed areas', a conclusion emphasized by A. J. P. Walter.

The papers contributed to the symposium were available as pre-prints, but a collected volume, including the discussion, is to be published.

K. C. DUNHAM

THE NATIONAL STANDARDS LABORATORY OF AUSTRALIA

DIVISION OF METROLOGY

THE work described in the annual report for 1956–57 of the Division of Metrology of the Australian National Standards Laboratory extends over a wide field and is of interest to the physicist and the engineer, to the laboratory worker and the industrialist, who are concerned with standardization and fine measurement. The primary objects of the work are the maintenance and improvement of the Commonwealth standards, the development of improved techniques of measurement and providing assistance to industry. The need for standardization and co-operation at international level is clearly recognized and accepted as an important responsibility; considerable effort has been devoted to this end, particularly in the field of length-measurements by the up-to-date techniques of optical interferometry. It has involved world-wide travel to participate personally in deliberations under the auspices of the International Committee of Weights and Measures and of the International Convention for Legal Metrology, and to make personal contact with those engaged in similar work in comparable institutions in other parts of the globe. Incidentally, the report from the section which deals with line standards indicates very clearly the difficulties of establishing and maintaining precise standards of length on the present basis of a material metre bar in the custody of an institution half the world away. Australia will stand to gain as much as any nation from the international adoption, envisaged for 1960, of a wave-length definition of the metre.

In this brief note one cannot hope to do full justice to the many activities reported, and the remaining comment will therefore be confined to a few points. For example, it is noticed that the National Standards Laboratory has been able to extend its help beyond the borders of Australia in the verification of standards of mass and that its own accuracy of weighing, already high, is to be refined by means of a special balance ordered for the purpose. The fact that the section leader responsible for this work is also concerned with such diverse matters as barometry, density, photogrammetry, measurements of time and fluid flow and the investigation of lapping techniques illustrates the breadth of the need for precise measurement and development in basic techniques.

In the general field of engineering dimensional metrology, assistance is given to industry by testing measuring equipment of all types, machine tools and workpieces, by advice on the design of precision measuring apparatus, and by providing practical help in the alignment of large-scale engineering structures. The air gauging technique is being applied to the development of special measuring equipment.

Other needs of the engineer receive the attention of the Applied Mechanics Section, which is responsible for the measurement of force (load), pressure and hardness, and conducts research in vibration, engineering design, production processes and the mechanical aspects of machining. This Section is equipped for the measurement of load up to 500 tons-force in compression and 50 tons-force in tension, for the measurement of hardness in the usual scales, and has deadweight pressure gauge testers ranging up to 30,000 pounds-force per square inch.

Particular attention has been paid to the factors governing the functional requirements of an engineering product in relation to production and inspection, and the results of analytical study of these factors are being widely disseminated by publication and lecturing. In parallel, and in support, research is being conducted to determine the factors in machining which control dimensional frequency distribution, tool wear and tool life.

A small but active Electronics Section has been busy applying electronic techniques to a variety of problems such as a pressure controller for barometry and the measurement of the periodic errors in machine tools and of cutting forces in research on machinability. It is to be expected that this Section will be expanded in due course in order to reap more fully the advantages in accuracy and flexibility which electronic techniques can bring to precise measurement.

Returning to the subject of vibration, it is recorded that the demand for vibration testing and consultative services have seriously reduced progress on main research projects and that certain of the Division's equipment has had to be moved to a site shown by a vibration survey to be less objectionable. The simultaneous growth of the need for more powerful machines and equipment and for greater refinement of measurement presents a growing problem of particular importance to all metrologists, a problem which will become increasingly difficult to solve without forethought on the part of all concerned.

The staff of about three dozen research officers and technical officers, helped by an equal number of technical assistants, during the year published nearly a dozen papers and had some half a dozen further papers ready for publication. Indicative of the high regard in which the work of the Division of Metrology is held is the recent appointment[1] of its chief, Mr. N. A. Esserman, as the first director of the National Standards Laboratory. This is stated to be one of the first consequences of the recommendations made by a committee of the Advisory Council which reported last year on the future development of the Laboratory. Mr. Esserman remains directly responsible for the work of the Division.

BRISTOL CITY MUSEUM

THE report of the City of Bristol Museum for 1957* continues the series of readable, well-produced and attractively illustrated publications issued annually by that Museum, in which it also continues to record a commendable extension of activities and responsibilities, evidenced by the introductory matter on the personnel and scope of committees and sub-committees on general museum work, on staffing and policy, on the preservation of ancient Bristol and on the Museum School Service. The latter, for years an informal advisory committee, has now become fully official, reflecting the increased volume of, and value placed upon, the work the Museum does for the schools of the area. It is presided over by the chairman of the City Museum and Art Gallery Committee, and its members include teachers serving in Bristol schools and representatives of departments of education.

Staff matters reflect the health of any museum. In this report, loyalty and long service to a respected institution are reflected in the retirement of the administrative assistant after forty-five years service —thirty-three years of which were with the Museum and Art Gallery—and of the museum foreman after twenty-two years. One member of the staff has obtained an M.A. degree and another the diploma of the Museums Association, while a third has left to take up a curatorial post in another institution. The director and staff also figure as officers or members of a variety of learned societies and advisory bodies, both national and local, and the list of research work accomplished and papers published is clear evidence of a busy institution.

The acquisition of Chatterton House, the birthplace of the boy-poet Thomas Chatterton, thanks to the generous intervention of the Dulverton Trust, adds to the many attractions Bristol Museum can offer. Temporary exhibitions continue to be a major offering to townspeople and visitors—a post-war feature of museums' activities, which take much time and give much trouble, but which are greatly worthwhile. The lenders range from the city librarian and city archivist to the Victoria and Albert Museum in London. Publications produced include a "Guide to Roman Buildings in Kings Weston Park" and leaflets on the Folk Museum at Blaise Castle House, as well as programmes of a highly successful series of winter lectures and summer conducted walks to places of historical or scientific interest in the neighbourhood. The services rendered are varied—from providing an attractive venue for official receptions given by the Lord Mayor, the Sheriff and the Vice-chancellor of the University of Bristol to housing a training course for students for the diploma of the Museums Association.

Departmental reports record valuable work on the coin collections, greatly used for reference purposes, new exhibits on African ethnology, primitive shipping, berries and twigs, British Lepidoptera for beginners and metalliferous mining in the Mendip Hills, and a new room devoted to Georgian costume as a contrast to the already popular Victorian room. The new Department of Conservation is proving its great worth and has a lengthy and interesting list of repairs completed, treatments accomplished, models made and exhibits prepared to its credit. Its organization has been greatly helped by the Works Laboratory of the Bristol Aeroplane Company—an interesting example of co-operation. Special reference is due to the work for schools, for which an additional assistant organizer has been appointed. Lessons in history, biology, geology and geography are given to an ever-increasing number of classes, and it is gratifying to note that children from nearly one-third of all the junior and secondary schools in Bristol attend, while the School Loan Services, with a better collection than ever before of specimens, models and photographs, are used by more than 70 per cent of the schools in the Bristol area. Teachers in training in seven institutions visit the Museum to learn how best to use museum facilities in their future professional practice. At the other end of the scale, the Saturday Club continues to enjoy an enthusiastic membership of young naturalists aged 9–11 years.

D. A. ALLAN

SOME PROBLEMS OF SMALL FIRMS

A SHORT report published by the Department of Scientific and Industrial Research gives details of one of the most encouraging services to industry carried out under its auspices*. It is a commonplace that the economic prosperity of Great Britain would be secure if a fair proportion of the many small firms and medium-sized firms could be brought up to a standard of efficiency equal to that of some of the bigger firms. One of the difficulties is that, hitherto, there has been an unbridged gap between research institutions with their store of valuable knowledge and the small and medium-sized firms who might well use this knowledge but lack trained scientists and technologists to guide them to it. This report describes the work of a technical liaison service which was organized in 1955–56 by the Scottish Council (Development and Industry), the broad purpose of which is to promote the economic development and well-being of Scotland. A team of three investigators, all men who had retired from responsible managerial or technical posts in industry, visited small and medium-sized engineering firms in the industrial belt of Central Scotland to find out what problems confront the smaller firms in the drive for greater efficiency and expansion; what equipment they possess for solving these problems for themselves; where to get help; and in what ways external sources could help.

During the survey the technical liaison service helped 109 firms, each with fewer than five hundred employees and with no elaborate management organization, to find solutions to 223 problems which they could not overcome with their own resources. Every interested firm was visited by a member of the team who helped to define each problem precisely and then to find a solution. Some questions could be answered on the spot from the member's own experience; the rest were referred to the Scottish Council's office in Edinburgh, where the technical co-ordinator of the project got in touch with the most likely sources of information.

The work of the experimental technical liaison service disclosed that:

(1) Firms in the survey were relying predominantly on trade contracts and other firms for information on new developments and techniques, and were accordingly in danger of operating within a closed circle.

(2) A few firms had ample technical resources, but most had few or none.

(3) Although many of the firms seemed to be attempting creative adjustments to new circumstances, only ten of them were managing to do so without introducing violent and disruptive changes. There were many reasons for this, but a predominant one was lack of technical information on which long-term plans could be based.

(4) Most firms were having difficulty in answering, from their own resources, some of the problems which affected their future plans; they discussed these with the technical liaison service.

(5) Half the problems had been previously abandoned, or were defined for the first time during discussions with the team, or with the staff of research and other organizations introduced by them.

(6) Answers to more than 70 per cent of the problems were found by the technical liaison service during the survey. The information required was in existence, but its sources unknown to, or unused by, the firms.

The outstanding success of the technical liaison service led the steering committee of the Scottish Council to recommend that a permanent technical liaison service should be provided; at first it would help small and medium-sized engineering firms, as the experimental service had done, but later it should be extended to other industries. The Committee indicated that the operation of regional schemes on these lines should be in the charge of the Department of Scientific and Industrial Research and suggested that the Secretary of State for Scotland should be asked if an official service could be provided. Meanwhile, the Committee felt that the service was so urgently needed that it should be run by a private Scottish institution until an official scheme could be established—preferably by an independent organization, like the Royal College of Science and Technology at Glasgow, since the experimental service gained much from the support of technical colleges and from easy access to technically qualified staff with industrial training.

The Scottish Education Department has recently authorized the expenditure required to set up a technical information service, on the lines proposed by the Scottish Council's steering committee, under the Department of Industrial Administration at the Royal College of Science and Technology, Glasgow. This extension of the Department's work is largely experimental and will be revised in not more than three years.

CONTRIBUTION OF HIGH-ENERGY PARTICLES TO THERMONUCLEAR REACTION RATES

By Dr. G. EDER
Institute of Theoretical Physics, University of Vienna

AND

Dr. H. MOTZ
Engineering Laboratory, University of Oxford

IN the course of work on a general study of the feasibility of thermonuclear power generation, we have examined the reactions :

$${}^2_1\mathrm{D} + {}^2_1\mathrm{D} \rightarrow {}^3_2\mathrm{H} + {}^1_0n\,(3\cdot265 \pm 0\cdot018)\,\mathrm{MeV.}\ \text{(ref. 1)} \quad (1)$$

$${}^2_1\mathrm{D} + {}^2_1\mathrm{D} \rightarrow {}^3_1\mathrm{T} + {}^1_1p\,(0\cdot0136 \pm 0\cdot022)\,\mathrm{MeV.}\ \text{(ref. 1)} \quad (2)$$

$${}^3_1\mathrm{T} + {}^2_1\mathrm{D} \rightarrow {}^4_2\mathrm{He} + {}^1_0n\,(17\cdot577 \pm 0\cdot02)\,\mathrm{MeV.} \quad (3)$$

In view of the recent experimental results obtained by means of ZETA at Harwell[2] it seemed to us worth while to communicate some of our results concerning thermonuclear reaction-rates. These results show in detail the contribution of particles of various energy groups to the total reaction-rates. It will be seen that in all cases considered the main contribution comes from a rather small number of particles with energy much higher than the mean thermal energy of the particles.

Attention was directed to this fact by Post[3], who points out that "the tail of the Maxwell distribution wags the dog". These results point to the possibility of using acceleration processes within a gas discharge for the purpose of production of fusion power. The Harwell results quoted above indicate that the neutron yield of ZETA is in fact due to non-equilibrium processes.

The reaction-rate in a hot plasma with nuclei of type A and of velocity $u = (u_1, u_2, u_3)$ and type B of velocity $v = (v_1, v_2, v_3)$ is given by :

$$R_{AB} = \int_{-\infty}^{\infty} f(u_1)\mathrm{d}u_1 \int_{-\infty}^{\infty} f(u_2)\mathrm{d}u_2 \int_{-\infty}^{\infty} f(u_3)\mathrm{d}u_3 \int_{-\infty}^{\infty} g(v_1)\mathrm{d}v_1 \int_{-\infty}^{\infty} g(v_2)\mathrm{d}v_2 \int_{-\infty}^{\infty} g(v_3)\mathrm{d}v_3 . \sigma(w) \quad (4)$$

where f and g are velocity distribution functions such that the particle numbers in a volume element of velocity space are given by :

$$\mathrm{d}n_A = f(u_1)\, f(u_2)\, f(u_3)\, \mathrm{d}u_1\, \mathrm{d}u_2\, \mathrm{d}u_3$$
$$\mathrm{d}n_B = g(v_1)\, g(v_2)\, g(v_3)\, \mathrm{d}v_1\, \mathrm{d}v_2\, \mathrm{d}v_3$$

and w is the absolute value of the relative velocity :

$$w = |\vec{u} - \vec{v}| \quad (5)$$

while $\sigma(w)$ is the cross-section of the reaction between A and B. When the velocity distribution is Maxwellian, it is easy to show from (4) that in a system where the nuclei B are at rest and the nuclei A have velocity w and kinetic energy $E = m_A w^2/2$:

$$R_{AB} = (8\pi n_A n_B/m^2_A)\,(m/2\pi kT)^{3/2} \int_0^{\infty} E\sigma_{AB}(E) \exp\,(-\,mE/m_A kT)\mathrm{d}E \quad (6)$$

where m is the reduced mass :

$$m_A \,.\, m_B \,/\, (m_A + m_B)$$

and $\sigma_{AB}(E)$ is the cross-section of the reaction between A and B.

Gamov and Teller[4] have shown that the cross-section for penetration of a Coulomb barrier of height $Z_A Z_B e^2/r_0$ between nuclei of atomic numbers Z_A and Z_B and masses m_A and m_B is given by :

$$\sigma_{AB} = A/E \exp(-\,B\,E^{-1/2}) \quad (7)$$

where

$$A = (m_A \pi \hbar^2/2m^2) \exp\,(4/\hbar)\,(2m\,Z_A Z_B e^2 r_0)^{1/2}$$
$$B = \pi Z_A Z_B\,\alpha_f (2m_A c^2)^{1/2}$$

and α_f is the fine-structure constant.

At low energy the fusion cross-section is of the form :

$$\ln E\sigma_{AB} = A' - E^{-1/2}B' \quad (8)$$

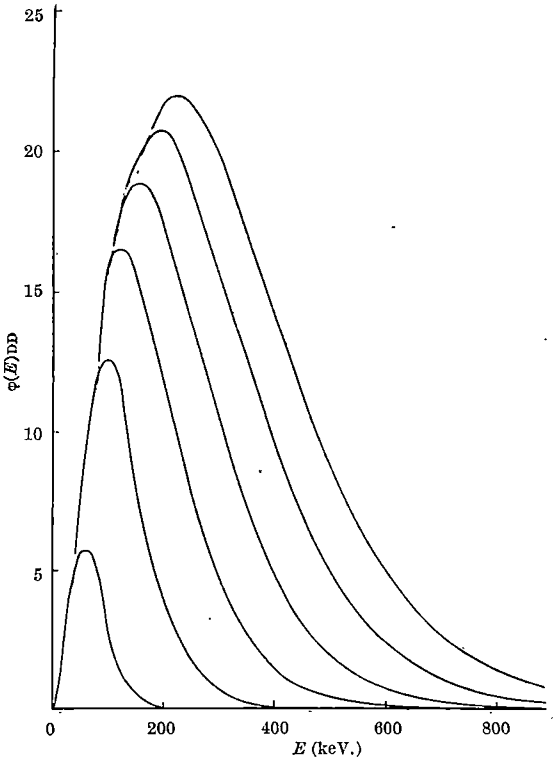

Fig. 1. Contribution to the reaction rate R_{DD} as a function of the deuteron energy E for kT = (left to right) 10, 20, 30, 40, 50, 60 keV.

We have determined the constants A' and B' from the experimental data for reactions (1), (2) and (3) as determined by Arnold and co-workers[5].

At higher deuteron energies for reaction (3) the experimental results of Argo and co-workers[6] were used. These experiments were carried out with triton beams of energy E_T in the laboratory system. Transforming to the system where the tritons are at rest the corresponding deuteron energies are given by:

$$E_D = (m_D/m_T)E_T = 0{\cdot}6677\ E_T$$

The cross-sections for reaction (2) have been measured by Wenzel and Whaling[7]. The total cross-section for reactions (1) and (2) has been determined by McNeill and Keyser[8] and the ratio of the cross-sections (1) and (2) has been determined by McNeill, Thoneman and Price[9]. Low energy measurements for reaction (2) by Moffat, Roaf and Sanders[10,11] are also available. We have computed the total reaction rate $R_{DD} = R_1 + R_2$ and $R_{DT} = R_3$, where the suffixes refer to the processes listed above. Formula (6) was used, which becomes:

$$R_2 = (n_\mathrm{D}\mathrm{cm.}^3)^2\ 10^{-21}\ \mathrm{cm.}^{-3}\ \mathrm{sec.}^{-1}\int_0^\infty \varphi_2(E)\ \mathrm{d}\ (E/\mathrm{keV.}) \quad (9)$$

where

$$\varphi_2(E) = 8{\cdot}733\ (kT/\mathrm{keV.})^{-3/2}\ \exp(-E/2kT)\ (\sigma_2(E)E/\mathrm{millibarn/keV.})$$

for reaction 2, and for reaction 3

$$R_3 = (n_\mathrm{D}n_\mathrm{T}\ \mathrm{cm.}^6)\ 10^{-17}\ \mathrm{cm.}^{-3}\ \mathrm{sec.}^{-1}\int_0^\infty \varphi_\mathrm{DT}(E)\ \mathrm{d}\ (E/\mathrm{keV.}) \quad (10)$$

with

$$\varphi(E)_\mathrm{DT} = 1{\cdot}622(kT/\mathrm{keV.})^{-\ /2}\ \exp\ (-\ 0{\cdot}5996\ E/kT)\ (\sigma_3(E)E/\mathrm{barn/keV.})$$

where all quantities are expressed in terms of the units indicated.

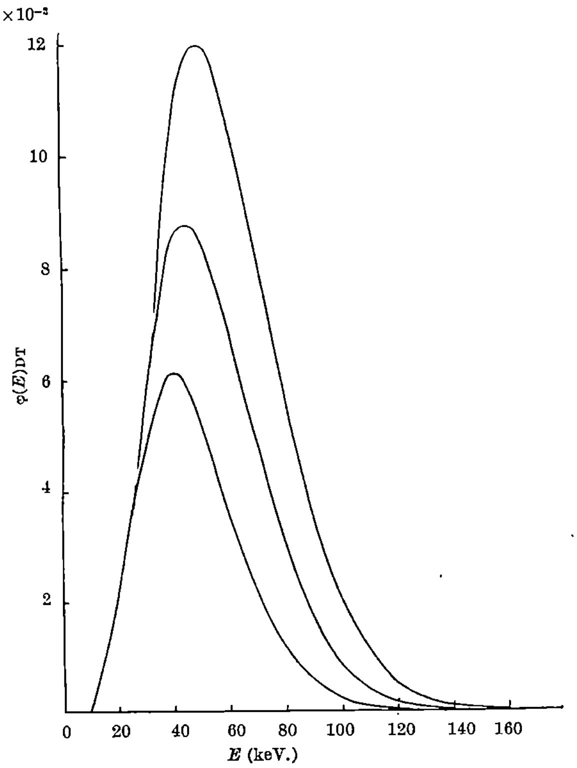

Fig. 2. Contribution to the reaction-rate R_{DT} as a function of the deuteron energy E for kT = (left to right) 6, 7, 8 keV.

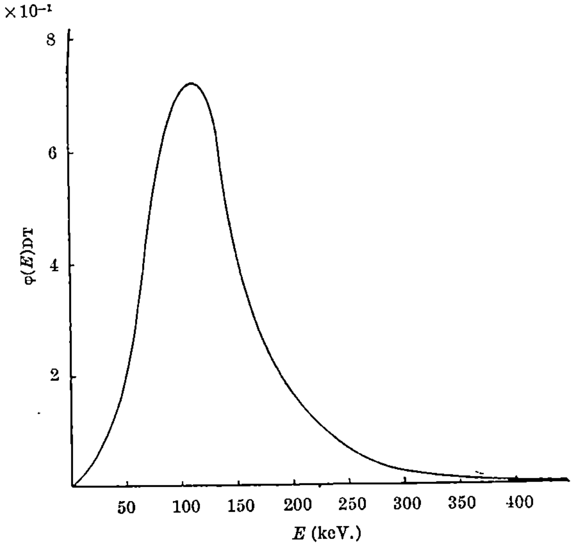

Fig. 3. φ_DT as a function of E for kT = 40 keV.

Fig. 1 shows φ_DD for temperatures of 10–60 keV. in steps of 10 keV. Fig. 2 shows φ_DT for temperatures of 6, 7 and 8 keV. Fig. 3 shows φ_DT for a temperature of 40 keV. It is seen that the reaction-rate is in each case mainly due to particles belonging to the tail of the Maxwell distribution. The total reaction-rates were computed in accordance with formulæ (9), (10) by integration over dE.

An approximation to the reaction-rate can be obtained by means of a method due to Gamov. One can write, in first approximation:

$$\int_0^\infty \varphi(E)\mathrm{d}E = \Delta E\varphi(E_m) \quad (11)$$

because the integrand is of the form

$$\varphi(E) = \exp\{-\ (mE/m_AkT) - B'E^{-1/2}\} \quad (12)$$

and has a sharp maximum as a function of E at $E = E_m = (B'm_AkT/2m)^{3/2}$. If ΔE is defined by:

$$\varphi(E + \Delta E/2) = \varphi(E_m)/e \quad (13)$$

ΔE is given by:

$$\Delta E = (32/3\ B')^{1/2}\ (B'm_AkT/2m)^{5/6} \quad (14)$$

In the results for the DD and DT reaction-rates which have been tabulated below, the values for E_m, the energy of the maximum contribution to the reaction-

8	48	60·51	6·52
40	110	748	25

rate, have been entered, together with the computed reaction-rates for various temperatures.

In Table 1 for the D–D reaction we have included the values of E_m and R_{DD} as computed from the Gamov approximation. It is seen that the Gamov approximation holds only for low temperatures.

It is interesting to compute the mean energy $m_D\overline{u^2}/2$ of deuterons in the laboratory frame of reference which have relative energy $E = m_D W^2/2$ on collision. Statistical analysis gives the result :

$$m_A\overline{u^2}/2 = \tfrac{1}{2}m_A\, W^2\, (m/m_A)^2 + 3/2\, kT\, (m/m_B) \qquad (15)$$

where m is the reduced mass.

Conversely, one can compute the mean relative energy on collision of deuterons with energy $m_D u^2/2$ in the laboratory system. The result is :

$$m_A\, \overline{W^2}/2 = m_A u^2/2 + 3/2\, kT\, (m_A/m_B) \qquad (16)$$

Using these results Tables 3 and 4 can be computed for D–D and D–T reactions :

Table 3. D–D REACTIONS

kT (keV.)	10	20	30	40	50	60
E_m (keV.)	59	94	124	150	174	196
$m_D\overline{u^2}/2$ (keV.)	22	39	54	68	81	94
$m_D u^2/2$ (keV.)	44	64	79	90	99	106

Table 4. D–T REACTIONS

kT (keV.)	2	4	6	7	8	40
E_m (keV.)	19·8	31·6	40·6	44·4	48·0	110
$m_D\overline{u^2}/2$ (keV.)	8·35	14·1	18·2	20·2	22·1	63·8
$m_D u^2/2$ (keV.)	17·8	27·6	34·6	37·4	40	70

The energies $m_D u^2/2$ have been computed from equation (16), where $m_A\overline{W^2}/2$ has been identified with E_m. They are thus the energies of deuterons which have a mean relative energy equal to the relative energy giving the maximum contribution to the reaction rate.

In Tables 1 and 2 there are columns headed 'per cent effective'. These are the percentages $\Delta n_A/n_A\,.100$ of deuterons with relative energy larger than E_m computed from :

$$\Delta n_A/n_A = n_B\, 4/\sqrt{\pi}\int_z^{\infty} z^2 \exp(-z^2)\, dz$$

where the lower limit of the integral is given by $Z = (mW^2/2)^{1/2}$ and m is again the reduced mass.

Looking at these tables one notes that ions with fairly low energies in the laboratory system have on average a high relative energy. This may be relevant when one is considering the effect on the reaction-rate of accelerated deuterons inserted into a discharge. Looking at Table 2 one notes that in the case of the D–T reaction the effective percentages are rather low, again showing that relatively few accelerated deuterons injected into a plasma may produce reaction-rates comparable to the purely thermonuclear ones. A complete discussion of these effects would, of course, have to include acceleration processes and energy loss of extra particles. Such studies are being undertaken at Oxford.

PERMANENT MOISTURE EXPANSION OF CLAY PRODUCTS ON AUTOCLAVING

By DR. J. S. HOSKING and DR. H. V. HUEBER
Division of Building Research, C.S.I.R.O., Australia

IN the course of a study of the permanent moisture expansion of clay products we have found that all such products so far examined expand once they leave the kiln and are exposed to the action of water or water vapour. We have also found that reproducible maximum or total expansions, usually many times greater than expansions so far reported, are obtained by autoclaving the kiln-fresh samples in saturated steam at elevated temperatures until stable dimensions have been attained, the actual temperature of autoclaving being unimportant. About 400 industrial and laboratory specimens have now been autoclaved for 24-hr. periods at 200° C. (225 lb./sq. in. absolute) until expansion ceased, and the average and range of the total moisture expansions (measured after drying for 48 hr. at 110° C.) for eight types of product are given in Table 1; curves for the average expansion with time for each of these products are given in Fig. 1, and the curves for two individual bricks, one light-burnt the other hard-burnt from the same kiln sampling, in Fig. 2. Because of the small numbers of some of the products examined so far, the values presented cannot be considered as completely characteristic, but they do indicate the general trends for the various bodies.

With values now available for maximum or total expansion, more reliable conclusions than have been possible in the past on the basis of incomplete

Table 1. PERMANENT MOISTURE EXPANSION FOR EIGHT TYPES OF CLAY PRODUCTS

Product	No. examined	Expansion	
		Average (per cent)	Range (per cent)

expansions may be drawn as to the influence of such factors as the temperature of the moisture to which they are exposed, raw materials or body composition, methods of manufacture and firing temperature on the rate and extent of the expansion of various bodies.

That the rate of expansion of ceramic bodies varies with the temperature of the moisture to which they are exposed has been observed by many workers[1–6]. This has not only been confirmed by the present work, but by recalculating our figures and those of Mattyasovszky-Zsolnay[3], Bullin and Green[4] and Smith[5] to the hours of treatment necessary to give the same expansions in one hour at 200° C., we have been able to show that the temperature coefficient of the rate of expansion, at least in the early stages, is similar for a wide range of bodies and temperatures of reaction. For ceramic bodies generally the average rate of expansion is shown to change approximately 1·8 times for each 10 deg. C. variation in temperature, a figure which may be compared with the usual value of about 2 for the temperature coefficient of chemical reaction.

The above workers believed that the extent of expansion was also affected by the temperature of the moisture, but since none of their measurements was continued until dimensional stability of the body was reached, it is now clear that what appeared to be an increased expansion is merely another expression of increased rate.

In studying the effects of body composition and temperature of firing on expansion, certain workers[1,2,7] concluded that for a given body composition the moisture expansion decreased as the firing temperature increased. Holscher[1] and Thiemecke[2] considered further that vitrified bodies did not expand at all. Bullin and Green[4] and Norris[8], however, showed that apparent reductions in expansion with increased firing temperatures were due to reductions in rate rather than in extent, and their conclusions are more in accord with our results. These show that while all bodies examined, including well-vitrified ones, expanded on contact with moisture, the relationships between expansion and firing temperature are most complex and cannot be expressed in general terms. The relationships vary according to the composition and structure of the different bodies, and for any particular body they depend on the stage in the progress of the expansion at which they are compared (Fig. 2). For some bodies the total expansion increases as the temperature increases up to the maximum of practical firing, in which case well-vitrified and bloated samples expand most of all. In some cases the relationships are reversed, in others the maximum expansions occur at an intermediate temperature, and for some bodies there is little difference in the amount of expansion throughout the whole firing range. In general, the rate of expansions of the light-burnt products is much faster in the early stages of reaction than that of the harder-burnt products, and the lighter-burnt products reach their total expansion in a shorter time.

A study of the expansion curves for many well-burnt products shows that the relationships between expansion and time may be expressed by the equation:

$$E_t = E_T\,(1 - e^{-kt})$$

in which E_t per cent is the expansion at any time t hours, E_T per cent is the total expansion, and k is a constant. Such an equation is similar to that for a first-order chemical reaction in which E_T is a function of the concentration of the components which on hydration give rise to expansion, E_t depends on the amount of material hydrated in time t, and k is the velocity constant. Hence, the reactions responsible for expansion obey first-order kinetics. For the hard-burnt brick the expansion of which is illustrated in Fig. 2, the derived equation, in which t

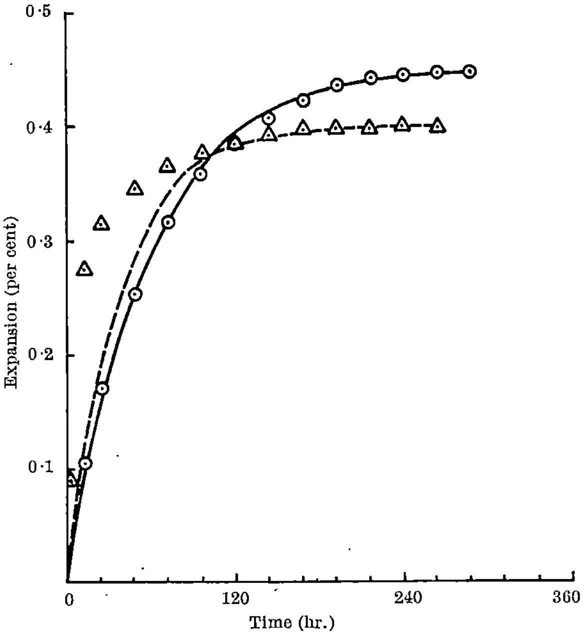

Fig. 2. Experimental and derived permanent moisture expansion for a light-burnt and a hard-burnt brick from the one kiln sampling. Hard-burnt: ⊙, experimental; ——, derived values. Light-burnt: △, experimental; – – –, derived values

is expressed in hours of autoclaving and 0·450 per cent is the total expansion, is :

$$E = 0{\cdot}450\ (1 - e^{-0{\cdot}018t})$$

and the good fit between the derived and experimental values is apparent.

When the similar equation :

$$E = 0{\cdot}403\ (1 - e^{0{\cdot}026t})$$

is applied for the light-burnt product and the experimental and calculated values are compared (Fig. 2), it is seen that although there is good agreement in the later stages of the reaction, expansion in the early stages is much faster than would be the case if the curve followed a simple first-order reaction as closely as does that of the well-burnt brick. It is considered that this difference in the behaviour of the two bricks is due to differences in the structures of the reactive compounds produced at the two temperatures. In the well-burnt body the reactive compounds are probably glassy, whereas in the light-burnt one they are probably non-vitreous amorphous silicates and dehydrated clay minerals with a much more open structure and larger surface-area ; hence the water is able to diffuse into the reactive compounds of the light-burnt body more rapidly, and expansion in the initial stages is at a higher rate than that in the hard-burnt body. Smaller differences between predicted and experimental values are found in bricks from the same sampling burnt at intermediate temperatures, and in which a change-over from non-vitreous to vitreous compounds undoubtedly occurs.

These investigations are proceeding, and full progress accounts are in course of preparation.

ANTI-TUMOUR AND BIOCHEMICAL EFFECTS OF PURIFIED BOVINE XANTHINE OXIDASE IN *C3H* AND *C* MICE

By PROF. A. HADDOW, F.R.S., DR. G. DE LAMIRANDE[*], PROF. F. BERGEL,
DR. R. C. BRAY and D. A. GILBERT

Chester Beatty Research Institute, Institute of Cancer Research : Royal Cancer Hospital,
Fulham Road, S.W.3

THE observation[1] that xanthine oxidase inhibits the growth of spontaneous mammary carcinoma in mice carrying the Bittner factor was discussed at a Ciba Foundation Symposium[2] in relation to the lower levels of the activity of this enzyme in the tumour cell when compared with the normal cells from breast tissue of low-tumour strain (*C* –) and high-tumour strain (*C* +) mice, as established by Lewin *et al.*[3].

It then became clear that further work ought to deal in an extended manner with the confirmation of the preliminary results and with the problem of the fate of injected xanthine oxidase in the animal organism. The second point required special attention as the xanthine oxidase concentrate used for the early chemotherapeutic experiments was of bovine origin, having a molecular weight of about 300,000. Criticism of the connexion between anti-tumour effects and enzyme properties could be based on the possibility that the 'foreign' protein might exert a non-specific action and that the large molecule might not be taken up by the mouse tissue or cells. In the following we wish to report on the outcome of recent investigations in both directions.

Chemotherapeutic experiments. The first trial run of the new series attempted a comparison between the effects on mammary tumours of *C3H* and *C* + mice of a xanthine oxidase concentrate from cow's milk[4] with a preparation which had lost most of its enzyme activity through storage but differed chemically and physico-chemically very little from the material with full catalytic activity[5]. Both concentrates ('active' : *AFR* = 90 ; 'inactive' : *AFR* = 6) were injected intraperitoneally twice daily using 10 mgm. doses of xanthine oxidase in 1 ml. saline, together with 0·2 mgm. of sodium salicylate. (Specific activities are expressed as *AFR* values[4] ; all the samples used in this and subsequent experiments had E_{280}/E_{450} (that is, *PFR*) values of about 7–8 ; weights of xanthine oxidase are calculated from E_{450} values[5].) Sodium salicylate had been found to stabilize the active enzyme considerably[6]. Perhaps because of the presence of salicylate, which is also an inhibitor of xanthine oxidase, the growth-rates of the tumours (measured in two perpendicular directions and expressed as surface area) were not slowed down very distinctly, though the impression was gained that in the mice treated with the active enzyme preparation the over-all effect was somewhat larger.

The next trial was carried out with active concentrates which were prepared following a differensequence of purification steps than for previout batches. The procedure, in some respects similar to that of Klenow and Emberland[7], consisted of treatment with butanol, ammonium sulphate fractions ation and calcium phosphate chromatography after enzymic digestion of buttermilk. In view of the above-mentioned difficulties the material containing salicylate was dialysed against sodium chloride and thus freed from the stabilizer-inhibitor a short time before use. The solutions had *AFR* values of 50–100, and 5 mgm. doses in 1 ml. of saline were injected daily intraperitoneally. A group of 18 tumour-bearing *C* + and *C3H* mice and an equally large control group which received saline injections were used. The results are graphically represented in Figs. 1*A* and *B*. Fig. 1*A* shows the mean relative tumour

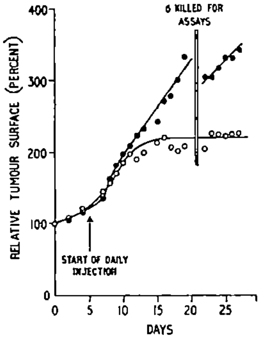

Fig. 1*A*. Experiment with eighteen *C3H* and *C*+ mice in each group. ●—●, Controls on saline injection; ○—○, animals treated with 5 mgm. xanthine oxidase daily. Relative tumour surface = (surface of tumours at each day × 100/surface of tumours at time zero)

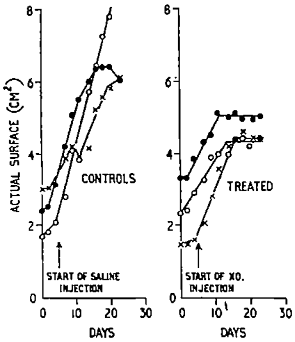

Fig. 1*B*. Actual tumour surface area of three representative individual animals from each group of Fig. 1*A*

surface for the respective groups, and Fig. 1*B* gives the actual surface values (cm.^{2}) of representative individual animals. Although the growth-rate of the tumours was variable a definite inhibitory action of the enzyme preparation could be observed. It is noteworthy that on cessation of the xanthine oxidase injections the tumours which had been arrested appeared to regain growth-rates similar to those of the controls, results which are not given in Figs. 1*A* or *B*.

Biochemical experiments. It was pointed out at the beginning that it was important to establish beyond doubt the accumulation of the extraneously introduced enzyme in measurable amounts in the organs of the mice. For this purpose the fate of injected milk xanthine oxidase was followed by quantitative assay in three ways. The levels of activity were estimated[3] in the intraperitoneal cavity and in the liver of *C* – mice after intraperitoneal injection of xanthine oxidase. An 'inactive' enzyme concentrate, bovine plasma albumin (Armour), 'supernatant' solutions from thermal denaturation of the enzyme and albumin and supernatant together were also studied. (The 'inactive' sample was prepared from a portion of the active one by irradiating with a tungsten lamp for 13 hr. The solution was immersed in a bath at 37° C. and stirred gently in an open vessel during irradiation. Water was added to make good the evaporation, and a slight precipitate was centrifuged off. The 'supernatant' solution was prepared by immersing a portion of the active enzyme solution in a boiling water-bath for 5 min. with protection from light and then decanting the clear solution.) Finally, the xanthine oxidase activity was measured in the tumour tissue and livers of treated and control *C3H* and *C* + animals.

Table 1. EFFECT OF INJECTIONS ON LEVELS OF XANTHINE OXIDASE ACTIVITY IN PERITONEAL CAVITY AND IN LIVER. ENZYME ACTIVITY:

Time after injection (hr.)	Intraperitoneal cavity			Liver		
	Intraperitoneal washings: 10³ units (ref. 4)		Per cent of injected dose	Total liver homogenate: 10³ units (ref. 4)		Per cent of injected dose
	Controls	Treated		Controls	Treated	
4	0	1·76	1·4	2·05	7·68	6·1
6	0	1·24	1·0	2·28	7·77	6·2
24	0	0·05	0·04	2·31	7·62	6·0

The treated *C* – mice received 5 mgm. (0·126 unit, ref. 4) of xanthine oxidase intraperitoneally. At the time of death, 2 ml. of 0·15 *M* sodium chloride were injected intraperitoneally to wash the cavity. The mice were massaged and then 1 ml. of the injected liquid was taken out. Determinations of xanthine oxidase were carried out on this liquid and on the excised livers. The controls were treated similarly with 0·15 *M* sodium chloride. All values are the mean of two determinations.

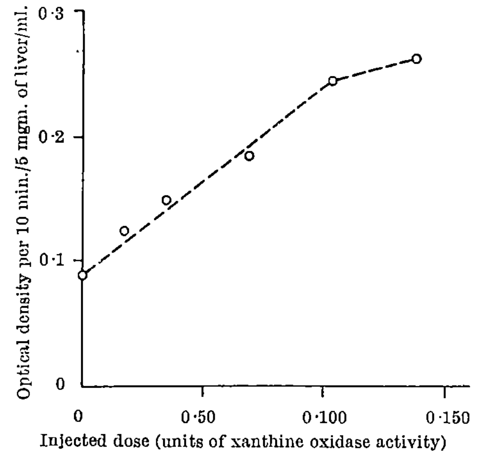

Fig. 2. Relation between liver xanthine oxidase activity and injected dose (in 2 ml. saline) 4 hr. after injection. The first point is the mean of determination on twelve *C* – mouse livers and the others of two. The livers were thoroughly washed in pyrophosphate buffer before homogenization

As can be seen from Table 1, washings of the intraperitoneal cavity still contained a measurable amount of the injected xanthine oxidase after four hours, this quantity falling to zero after 24 hours. An assay of the liver of the same animals indicated a substantial rise in the level of enzyme activity over the controls. It was then decided to test different amounts of xanthine oxidase to see whether the increase in the liver depended on the quantity of enzyme injected. As Fig. 2 shows clearly, the increase of xanthine oxidase activity in the liver is practically proportional to the dose up to about 0·1 unit, at which value the curve begins to level off. In another experiment the effects of the enzyme were compared with those of various other injections as mentioned before (Fig. 3). Active xanthine oxidase

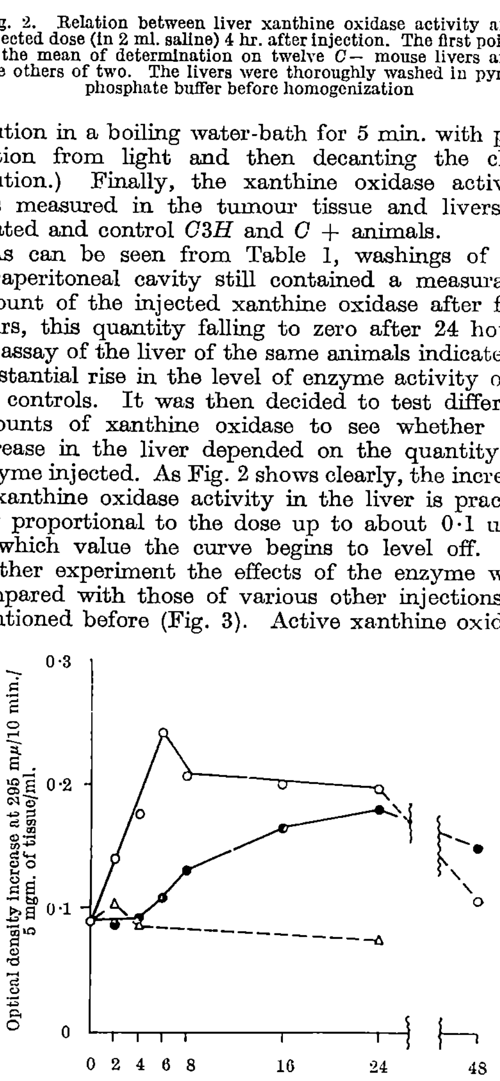

Fig. 3. Effect of injections on liver xanthine oxidase activity. Active xanthine oxidase: *AFR* = 95; 5 mgm. in 1 ml. saline. 'Inactive' concentrate *AFR* = 4; 5 mgm. in 1 ml. saline. Supernatant from equivalent of 5 mgm. enzyme. Crystallized bovine plasma albumin (Armour) 10 mgm. in 1 ml. saline or in 1 ml. of supernatant. The first point is the mean of determinations of twelve *C* – mouse livers and the others of three. The livers were thoroughly washed in pyrophosphate buffer before homogenization. ○—○, Active xanthine oxidase; ●—●, 'Inactive' xanthine oxidase; ◁—△, albumin, supernatant or both

Table 2. EFFECTS OF XANTHINE OXIDASE INJECTIONS ON TUMOUR-BEARING ANIMALS

	No. of animals	Mean xanthine oxidase activity 10^5 μmoles/min./mgm.	
		Tumour	Liver
Treated	4	24·4	40·0
Controls	6	10·0	14·3

Some tumour-bearing mice, from Fig. 1*A*, were killed after fifteen daily injections of xanthine oxidase or saline. The tumour tissue and the livers were used for xanthine oxidase assays; the activity is expressed in terms of uric acid formed per mgm. of fresh tissue.

increased the liver activity to 2·75 times that of the normal liver, 6 hours after injection, whereas bovine albumin and the supernatant were without effect. On the other hand, 'inactive' enzyme gave an increase to twice the normal level, the maximum effect occurring later than with the active preparation, namely, about 24 hours after the injection. This time-lag suggests that the inactive material is reactivated in the tissues of the mice.

Finally, Table 2 shows that in treated *C3H* and *C* + animals bearing tumours, not only the livers but also the tumour itself shows a higher xanthine oxidase activity-level than in the controls.

Conclusions and further outlook. From the results, just reported, it can be concluded that xanthine oxidase, even from a different species, can hold up the growth of spontaneous mammary tumours in *C3H* and *C* + mice. This is accompanied by an increase of the activity levels of xanthine oxidase in the livers and tumours of the treated animals. In experiments with *C* − animals it could also be demonstrated that the bovine enzyme causes an increase of the xanthine oxidase of liver, the levels being dependent on the amounts injected. 'Inactive' enzyme preparation was apparently reactivated in the liver but gave less rise than the concentrate with full enzymic activity. On the other hand, neither the 'supernatant' fraction nor bovine albumin or a combination of both produced any effects. While all this suggests strongly that the active xanthine oxidase molecules penetrate into the liver and tumour of the animals, and explains to some extent the observed changes in growth-rates of the tumours, it does not explain the underlying mechanism. It could be a case of replacement therapy, the injected xanthine oxidase making good the apparent deficiency in the tumour tissue. Whether this leads to an increase in purine catabolism, or a removal of growth-promoting pteridines or is simply an effect of increased intracellular hydrogen peroxide production, can only be decided after further work has been carried out. Tests on other tumours deficient in xanthine oxidase, such as the Novikoff hepatoma[8], assays of excretion of xanthine metabolites in urine, estimation of pteridines, studies of the effect of short[9] and long-term[2] application of xanthine on endogenous xanthine oxidase, could help in finding out more about our results. Only then could one think of extending the chemotherapeutic investigation to include combinations of xanthine oxidase with other related enzymes or with drugs, and to attempt, after immunological and pharmacological tests, corresponding trials in human patients.

We acknowledge the considerable help given by Mr. C. Smith in handling the animals and the technical assistance by Messrs. P. Trumper, A. Green, B. Mansfield and Miss A. M. Scott. GAS CHROMATOGRAPHIC TERMS AND DEFINITIONS

By MARCEL J. E. GOLAY

Perkin-Elmer Corporation, Norwalk, Conn.

IN several discussions I have had with workers in the field of gas chromatography, it appeared that much clarification remains to be achieved in nomenclature and definitions of terms, and that two causes of confusion stand out. The first is the ambiguous meaning of height equivalent to a theoretical plate (HETP); the second is the impossibility of drawing precise conclusions about the resolution (or resolving power) of a chromatographic column from a knowledge of the number of theoretical plates of that column, regardless of which of the two available definitions of the height equivalent to a theoretical plate is adopted. Both causes of confusion lose relevance when the retention-time of sample components, t, becomes very large when compared with the retention-time of inert gas packets, t_a, but the validity and usefulness of a system of terms and definitions should extend to those cases where t is no longer very large when compared to t_a.

The height equivalent to a theoretical plate has been defined[1] as that height of individual column portions which, if lumped into as many separate funnels of a Craig's machine, will cause the column so transformed to reproduce, in theory, the observable times t, t_a and Δt of the elution curves. When Δt designates the 'band-width at mid-height', the definition given leads to the following number of theoretical plates in a column[2]:

$$n_0 = 8 \ln 2 \frac{t(t - t_a)}{(\Delta t)^2} = 5{\cdot}54 \frac{t(t - t_a)}{(\Delta t)^2} \qquad (1)$$

The height equivalent to a theoretical plate has also been defined as that height of individual column portions which, if lumped into as many continuous absorption vessels[3], will cause the column so transformed to reproduce, in theory, the observable times of the elution curves. With this more usual definition, which will be the one adopted here, the number of theoretical plates is given by:

$$n = 5{\cdot}54 \, \frac{t^2}{(\Delta t)^2} \qquad (2)$$

The height equivalent to a theoretical plate thus defined can be connected in a simple manner with certain column characteristics. For example, if tu(cm.^{2}) designates the second moment, with respect to the column abscissa x, of a component distribution of total mass normalized to unity, the height equivalent to a theoretical plate (cm.) represents the increase of this second moment as the component packet travels 1 cm. in the column:

$$\text{HETP} = \frac{du}{dx} \qquad (3)$$

If the column consists of a capillary tube, uniformly coated with a retentive layer within which diffusion time is negligibly small, the following equation can be derived for the quantity above[4]:

$$\frac{du}{dx} = 2\frac{D}{v_0} + \frac{1 + 6k + 11k^2}{24(1+k)^2}\,\frac{v_0 r_0^2}{D} \qquad (4)$$

where D(cm.^{2} sec.$^{-1}$) is the rate of diffusion of component molecules in carrier gas; v_0 (cm. sec.$^{-1}$) is the average speed of carrier gas; and $k = (t - t_a)/t_a$ is the ratio of fixed phase capacity to moving phase capacity for the component; while r_0 (cm.) is the radius of the capillary.

It should be particularly noted that the very simple first term of the right-hand side of equation (4) represents the static diffusion term and corresponds to the second term of van Deemter's equation[5]. No other definition of the height equivalent to a theoretical plate can lead to a term in D/v_0 as simple as the one above, which should always be found (with a tortuosity factor γ for packed columns) in any theoretical expression purporting to connect the height equivalent to a theoretical plate with physical column parameters.

But the real measure of a column's efficiency is the resolution or resolving power of this column, that is, the potential ability of the column to separate two substances which differ but little in their affinity for the fixed (liquid or solid) phase. This resolution will be defined here as the inverse of the 'relative band-width', $\Delta t/(t - t_a)$:

$$R = \frac{t - t_a}{\Delta t} = \frac{k}{1+k}\,\frac{t}{\Delta t} \qquad (5)$$

When R is known for a given column and for one of a given pair of closely similar components, the 'relative separation', S_{12}, achievable for these components—the ratio of their actual time separation in the elution curve, Δt_{12}, over the band-width of one or the other, Δt_1 or Δt_2—will be immediately calculable from R and from the ratio of the partition coefficients, C_1 and C_2, of these components for the fixed phase, this ratio being a dimensionless physical quantity depending solely upon the nature of the two components and of the fixed phase, and not upon any design parameter of the column. Let ε designate the Naperian logarithm of the C_2/C_1 ratio. We have, with very good approximation:

$$S_{12} = \frac{2\Delta t_{12}}{\Delta t_1 + \Delta t_2} = R\,\frac{2(C_2 - C_1)}{C_2 + C_1} = R\varepsilon \qquad (6)$$

It is noted that the quantity of decisive interest, R, cannot be unambiguously derived from n (nor from n_0) as defined above. This is really as it should be, for a decision about the optimum k should be made, before R can be determined from the relation:

$$R = \frac{k}{1+k}\sqrt{\frac{n}{5{\cdot}54}} \qquad (7)$$

It is at this point that the performance index (P.I.) may be brought into play to help decide the optimum k, and thus to constitute the needed link, based on a physical theory, between fabricating parameters, such as the number of theoretical plates, and operating parameters, such as the resolution. The performance index was originally introduced[6] as a quantity which is nearly invariant in 'ideal' capillary columns (namely, columns in which the diffusion-time in the fixed phase is negligibly small), operated at the optimum flow-rate, and which could serve as a measure of the intrinsic goodness of a column. Since the publication of the original communication[6], a more rigorous theoretical treatment of capillary columns has been made, and this led to the slightly modified definition given below, in which the factor 15/16 has been substituted for the former factor 3/4 [7]:

$$\text{P.I.} = \frac{(\Delta t)^4\, t_a\, \Delta p}{t^3(t - 15t_a/16)} \qquad (8)$$

where Δp designates the drop in pressure across the column. When the performance index is written as follows:

$$\text{P.I.} = \left(\frac{\Delta t}{t - t_a}\right)^4 \cdot \frac{(t - t_a)^4\, t_a}{t^4\,(t - 15t_a/16)} \cdot t\Delta p \qquad (9)$$

the first factor of the right-hand side is recognized as $1/R^4$ and should therefore be minimized, and if the last factor, $t\Delta p$, constitutes a pre-assigned experimental boundary condition, then optimum performance will be obtained for the value of k which maximizes the middle term:

$$k_{\text{opt}} = \left(\frac{t - t_a}{t_a}\right)_{\text{opt}} = 3{\cdot}1 \qquad (10)$$

a very small departure from the previously[6] reported optimum k (3·3).

Δt has been used here to designate the band-width at mid-height, a rather popular usage. Another parameter, proposed by Keulemans[8], is the width intercepted on the base line by the tangents at the inflexion points of the band. I would like to urge that the already much-used terms 'band-width', or 'peak-width' and their symbol Δt, be continued in use in their established connotation of width of band at mid height, and that the term 'band intercept' or 'peak intercept', and the symbol $\Delta_i t$, be utilized to designate Keulemans's proposed measure.

A New Phenomenon of Electron Emission from Thin Mercury Films

When describing a new power rectifier valve utilizing line emission from the wetting edge of a mercury pool[1], the observation of a new phenomenon of emission was mentioned. At low loads, luminous patches had appeared for short instants parallel to the emission line in places on the anchor where film-like condensation had occurred. The luminous patches started on the film of condensate without visible initiation by a cathode spot from the emission line.

Emission into a mercury vapour arc from an extended area is in striking contradiction to the present concept of emission from liquid surfaces; hence, reproduction of the observed phenomenon over periods of sufficient length of time for proper observation promised a new way of approach to the mechanism of emission from liquid surfaces; further, it could yield valuable improvements for power rectifiers.

After more than three years of technological difficulties, a system satisfying stringent high-vacuum conditions has been produced. Fig. 1 shows its critical part under operating conditions. The emission system consists of a well-defined molybdenum surface (A) of about 1 cm.^{2} where the temperature can be adjusted at will between 20° and 70° C. This is enclosed in a discharge vessel with several electrodes and a reservoir, filled with about 1·5 cm.^{3} of liquid mercury. The walls of the discharge vessel, except the cathode surface A, are kept at a uniform temperature, variable between 20° and 350° C. Inflow of vapour towards the cathode system is thus determined by the temperature of the cathode and the vessel; excess condensate, if building up, returns in droplets to the reservoir. A protective conical screen (B) of thin molybdenum sheet extends from the temperature-controlled area down into the mercury reservoir, and prevents damage to the glass seal by the discharge. The discharge current covered the range 1–30 amp.

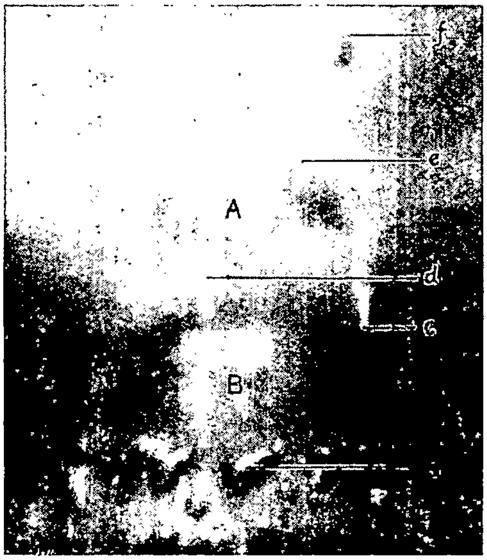

Fig. 1

A number of different phases of the emission, largely varying in appearance according to the specific operating conditions chosen, have been obtained, and also maintained for any desired length of time. These phases are: (i) the well-known free spots, running at random around on the spare mercury and the condensate droplets on surface A and cone B; (ii) transitional stages, consisting simultaneously of spots and fragments of lines moving at random with a preference for surface A; (iii) a multitude of streamers, emanating from the border between A and B, mostly extending on to A, but eventually also leading downwards on B, either alone or in combination with (ii); (iv) a uniform and steady glow-like thin sheath of small luminosity, evenly covering and clearly restricted to the surface part A, a phase for which the term 'film emission' will be used in the following.

The case shown in Fig. 1 is a transitional stage consisting of a short emission line (c), a number of streamers (d) and a patch of film emission (e); total emission current was 23 amp.; f is the ignition needle and g indicates large droplets of condensate.

Film emission, exclusively, can be obtained over a wide range of current densities; at very low values or with insufficient vapour density at the emission surface, the even spreading ceases, and contraction to lines, streamers or spots takes place. This behaviour suggests that the steady low current-density form of emission without evaporation represents the true and simple emission mechanism, while the more complex phases with random motion appear to be the unsuccessful attempts of the true mechanism to create those operative conditions which are required for the most favourable emission conditions.

It is too early to advance a theory of film emission. So far as observations go, they could be equally well interpreted by a current at the cathode composed overwhelmingly of electrons, or half of ions and half of electrons. In the first case the emission mechanism is a greater mystery than ever, because the current densities are several orders of magnitude too low for the mechanisms so far proposed. In the second case, one would have to postulate the release of about one electron per ion at the cathode surface, and a rather surprisingly efficient ionization mechanism in the region of cathode drop, which produces about one ion pair per electron. It is hoped that this will be decided directly by experiments now planned.

Because the film emission occurs at a definite place and is restricted to well-determined areas, clarification of the many rather conjectural assumptions made in the present theories of spot emission may be expected. One conclusion can be made already with certainty, namely, that emission from surfaces of liquid metal does not require intrinsically current densities of the order of thousands or ten thousands of amperes per square centimetre; neither does it require evaporation of the metal. For the further study of the emission of liquid surfaces, theories based on high current densities and evaporation of cathode material thus cannot claim universal validity.

My thanks are due to Prof. D. Gabor for putting at my disposal the resources of his laboratories at the

Imperial College of Science and Technology, London, and for his constant encouragement.

Elastic Constants of Diamond

IN a recent communication in *Nature*, Krishnan, Chandrasekharan and Rajagopal[1] suggest that discrepancies between the determinations of the elastic constants of diamond may find an explanation in the enlarged scheme of elastic constants suggested by Laval, LeCorre, Viswanathan and Raman. In referring to the results of the experiments by Prince and Wooster[2], they suggest that "probably the theory of diffuse scattering of X-rays needs some modification in the light of the new theory of elasticity".

In the following communication, we indicate what changes the new theory of elasticity introduces into the interpretation of the measurements of Prince and Wooster, with the same notation as used in their paper, and using for the new theory the notation of the Indian school (which differs from the one originally introduced by Laval in that their d_{45} is his N_{47}, etc.). The change introduced by the new theory consists in the coupling together of d_{12} and d_{45} to form an inseparable pair of constants. For example, the experiments on a 110 reflexion enable the intensities of diffuse scattering from points along the [110] and [001] directions to be compared. The corresponding K-ratio, $K[110]_{220}/K[001]_{220}$, is in the old theory: $2c_{44}/(c_{11} + c_{12} + 2c_{44})$, and in the new theory: $2d_{44}/\{d_{11} + d_{44} + (d_{12} + d_{45})\}$. Similar changes are introduced into the other K-ratios.

On the old theory the following ratios for the elastic constants were found:

$$c_{12}/c_{11} = 0{\cdot}30 \pm 0{\cdot}02, \quad c_{44}/c_{11} = 0{\cdot}40 \pm 0{\cdot}02$$

We repeated the calculations using this time the formulæ of the new theory, and obtained for the new ratios:

$$(d_{12}+d_{45})/d_{11} = 0{\cdot}70 \pm 0{\cdot}02, \quad d_{44}/d_{11} = 0{\cdot}40 \pm 0{\cdot}02$$

The absolute value of the constant d_{44} was measured by Prince and Wooster using the intensity of Compton scattering as the standard. This gave a value of $(44 \pm 2{\cdot}5) \times 10^{11}$ dyn. cm.$^{-2}$. (These units will be used throughout this communication.) Using the above ratio for d_{44}/d_{11}, the value:

$$d_{11} = 110 \pm 11$$

is obtained. To proceed further, it is necessary to consider the bulk modulus of elasticity. The bulk modulus, k, is connected with the elastic constants by the equation:

$$k = (d_{11} + 2d_{12})/3$$

The value of k given by Adams[3] is 63, and by Williamson[4], 56. They lead to the following values of d_{12}:

$$\begin{aligned} d_{12} &= 39 \pm 6 \text{ (Adams)} \\ &= 29 \pm 6 \text{ (Williamson)} \end{aligned}$$

Now, $d_{12} + d_{45} = (0{\cdot}70 \pm 0{\cdot}02)d_{11} = 77 \pm 10$, and hence:

$$\begin{aligned} d_{45} &= 38 \pm 16 \text{ (Adams)} \\ &= 48 \pm 16 \text{ (Williamson)} \end{aligned}$$

Table 1 summarizes the results calculated according to the two theories:

Table 1

Old theory	New theory (with Adams's k)	(with Williamson's k)
$c_{11} = 110 \pm 11$	$d_{11} = 110 \pm 11$	110 ± 11
$c_{12} = 33 \pm 5$	$d_{12} = 39 \pm 6$	29 ± 6
$c_{44} = 44 \pm 2{\cdot}5$	$d_{44} = 44 \pm 2{\cdot}5$	$44 \pm 2{\cdot}5$
	$d_{45} = 38 \pm 16$	48 ± 16

Unfortunately, the uncertainty in the diffuse X-ray measurements, combined with the uncertainty in the measurement of the compressibility, make it impossible to establish a significant numerical difference between d_{44} and d_{45}. The same uncertainty in the compressibility affects all the calculations of d_{45} based on the dynamically measured $(d_{12} + d_{45})$. Consequently it is hard to see how any experimental proof can at this stage be given that the classical three elastic constants are insufficient for diamond, and that the four constants of the new theory have to be applied to it.

Quite apart from these experimental considerations, we have suggested in a recent communication[5] that in those cases where the Laval theory is applicable the number of independent elastic constants is not 45 but 39. For the Laue-group *m3m*, to which diamond belongs, the number of independent elastic constants turns out to be three, the same as in the classical theory.

Furthermore, it is difficult to accept the view that a separation of the results of methods that are all essentially dynamic, into 'static constants' and 'wave (dynamic) constants', can be made in the way suggested in the communication by Krishnan *et al.*[1].

Errors in the Measurement of Film Thickness by Multiple-Beam Interferometry

THE Tolansky[1] method for the measurement of the thickness of thin films by multiple-beam interference techniques is now well established. Briefly, the film, the thickness of which is to be measured, is deposited on a flat, smooth substrate. The film should have a sharp edge so that a step is formed when the film and the adjacent substrate are coated with an opaque, highly reflecting metallic layer. The height of this step is measured by using the highly reflecting layer as one surface of an interferometer and viewing the multiple-beam fringe system by reflexion. Provided that the overlayer assumes the exact contour of the surface, this step-height will give the thickness of the film underneath.

There are two ways in which a sharp edge can be given to an evaporated film. Part of the substrate can be shielded during the deposition of the film, the shield being removed for the deposition of the overlayer. Alternatively, Scott, McLauchlan and

Sennett[2] have suggested that a sharp-edged step could be formed by gently drawing a not-too-sharp needle across the film prior to the deposition of the overlayer so that the film is removed, leaving a clear channel. However, they point out that care must be taken not to mar the substrate, in their case glass, marring being detected by the shape of the fringes.

In the course of investigating the adhesion of thin films to glass[3], it was found that serious errors could be made in the measurement of the thickness of the films when the method described by Scott, McLauchlan and Sennett was used. A number of metals were investigated, and in each case a film of the metal was deposited by evaporation on to a glass surface, a sharp edge being given to each film by covering part of the substrate during deposition. A number of channels was also made in each film by drawing a loaded steel point of smooth contour across the film surface. The point used in this investigation had a tip radius of 0·003 cm. and the load on the point was varied from 0 to 500 gm., the glass substrate tending to crack at this upper limit. The film and the substrate were then coated with an opaque silver layer and the film thickness and the depths of the channels or scratches were measured by viewing the multiple-beam interference fringes of equal thickness by reflexion. The results of one such set of measurements are shown in Fig. 1. In this case, the thickness of a chromium film was found to be 302 A., but the depth of the scratches made at loads greater than about 5 gm. were always greater than this value and increased with the load on the point. It has been shown[4] that plastic deformation of the glass substrate occurs when a load exceeding 2 gm. is applied to a point of tip radius 0·003 cm. pressing on it. It was found that the load required on the point to give a clear channel depended upon the adhesion of the metal film to the glass substrate and, for nearly all the films examined, a load greater than 2 gm. was required to give a clear channel. Therefore, deformation of the substrate would occur. Variation of the tip radius of the point would not eliminate the deformation of the substrate since it has been shown[4] that when the radius is decreased plastic deformation occurs at even lighter loads, whereas, when the radius is increased, a greater load is required to give a clear channel.

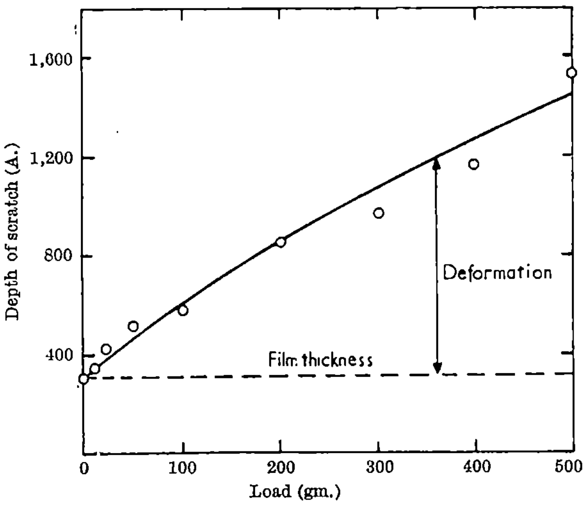

Fig. 1

Table 1

Metal	Load for clear channel (gm.)	Deformation of substrate (A.)
Silver	7	23
Gold	2	0
Copper	30	160
Aluminium	5	18
Antimony	—	—
Chromium	100	273

Scott, McLauchlan and Sennett measured the thickness of films of silver, gold, copper, aluminium, antimony and chromium. Table 1 shows the load on a point of radius 0·003 cm. required to give a clear channel in films of these metals together with the deformation of the substrate. It can be seen that if the depth of the channel was taken as the film thickness then very serious errors could occur, especially if the film adheres strongly to the substrate and a large load is required to give a clear channel. Scott, McLauchlan and Sennett have stated that a check was made between the film thickness and the depth of the channels and good agreement was found. However, it is possible that this check was made on a poorly adherent film such as silver, where the discrepancy would be within the experimental error, and this would account for the agreement.

It can be seen that even when a light pressure is applied to a point to give a channel by which the thickness of a film may be measured serious errors occur. These errors are even greater when excessive pressure has to be applied to the point to obtain a clear channel in a film which adheres strongly to the substrate. It appears that this method of forming a sharp edge to the film is unsatisfactory, and any measurements made using this technique should be treated with caution.

One of us (P. B.) wishes to thank the Metropolitan-Vickers Electrical Co., Ltd., for the provision of a postgraduate scholarship to undertake this work.

Calculation of Absorption Peaks in Thin Metal Films

The refractive index of an absorbing medium can be written as $N = n - ik$, where n and k refer to the real and imaginary components of the complex quantity N. In this notation the value of n retains the velocity relationship of a simple non-absorbing medium, and k is the extinction coefficient. Another form of the equation has, however, found common usage, particularly with early workers in the field of metal optics ; in this form the refractive index N' is defined by $N' = n'(1 - ik')$. It can be seen that N is related to N' by the equations $n = n'$ and $k = n'k'$.

Confusion between these two forms has led to some errors in the evaluation of data recorded in standard

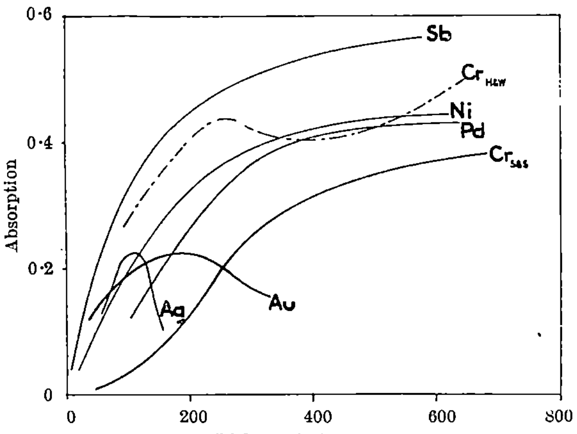

Fig. 1

reference books, for the quantities are commonly listed as n and k with no obvious correlating expression. Sennett and Scott[1] have been led into this type of error in an estimation as to the presence of peaks in the absorption/thickness curves for very thin metal films. Using Maxwell Garnett's equations[2], which are based on a theory of spherical aggregation within the metal films, they deduced that for a peak to be present in the absorption curve a quantity K, given by:

$$K = 2(k^2 - n^2)^3 - 9(k^2 - n^2)^2 + (12 + 8n^2k^2)(k^2 - n^2) - 4 - 12n^2k^2 \quad (1)$$

would have to be positive. Listed in Table 1 are the values that they obtained for K using values for the refractive indices of the metals listed in the International Critical Tables[3]. The variation of absorption of these metals with thickness is given in the full line curves in Fig. 1. From equation (1) it can be seen that the notation used by Sennett and Scott is that defined here by N, but the values of the refractive index components taken from the Tables correspond to $N' = n'(1 - ik')$.

Table 1

Metal	Wave-length	$N = n - ik$		K (ref. 1)	K (recalculated)
		n	k		
Silver	5890 A.	0·18	3·71	$+1{\cdot}5\times10^6$	$+3{\cdot}7\times10^3$
Gold	4000 A.	1·58	1·78	$-1{\cdot}07\times10^2$	$-49{\cdot}7$
	5800 A.	0·42	2·79	$+1{\cdot}7\times10^5$	$+5{\cdot}28\times10^2$
Copper	3950 A.	1·17	1·76	$-5{\cdot}3$	$+7{\cdot}44$
	6000 A.	0·56	3·08	$+5{\cdot}2\times10^4$	$+1{\cdot}09\times10^3$
Aluminium	5890 A.	1·28	4·69	$+2{\cdot}0\times10^3$	$+1{\cdot}87\times10^4$
Antimony	5890 A.	3·04	4·95	$-2{\cdot}6\times10^3$	$+3{\cdot}01\times10^4$
Nickel	5890 A.	1·79	3·33	$-35{\cdot}0$	$+1{\cdot}05\times10^4$
Palladium	6000 A.	1·92	2·52	$-2{\cdot}7\times10^2$	$+2{\cdot}32\times10^2$
Chromium	6080 A.	3·28	4·30	$-4{\cdot}4\times10^3$	$+4{\cdot}28\times10^4$

The values of K have been recalculated, using the corrected values for the refractive indices (Table 1, column 6), and little agreement has been found between the sign of K and the presence of absorption peaks. Furthermore, it is not considered likely that properties of this type, depending as they do on the conditions of preparation of the films, could be forecast with any accuracy from bulk metal values of refractive index. The Maxwell-Garnett model assumes the presence of a large number of discrete, spherical particles separated by free space, and as Sennett and Scott have already shown in the case of silver films[1] this holds only for very small values of film thickness. Thicker films show a much more continuous structure, which may or may not possess bulk properties. The transition from one structure to the other has been shown by a variety of experimental methods[4,5], and in all cases the properties being measured change widely with film thickness. Where, however, a film could be induced to grow as a series of perfect monolayers, each possessing the same optical properties, then the refractive index would remain constant, and for large thicknesses bulk material would be obtained. For this type of model structure measurements made on the bulk material would give valid results for thinner films.

In the course of an investigation into the structure of evaporated chromium films it has been shown that the optical constants vary widely with the thickness of the films[6], and that the effective refractive index of the complete film is not at all like that of the surface. Indeed, close agreement has been found between the effective refractive index of the surface layer of a thick film of chromium and of the bulk metal[7]. In this investigation the absorption curve was obtained and this is shown dotted in Fig. 1. The refractive index of the surface layer using the notation $N = n - ik$ was measured as $1{\cdot}18 - 0{\cdot}944i$, and the effective refractive index of the whole film was measured as $0{\cdot}64$–$1{\cdot}25i$; the former gave a value of K of $-30{\cdot}2$, and the latter $-0{\cdot}72$. As the growth has been shown not to follow the Maxwell Garnett pattern, little agreement could be expected and a peak was obtained in the absorption curve. The particles of these chromium films have, however, been found to follow more closely the David–Schopper[8,9] model of ellipsoids of revolution, but in this case differentiation of the equation for the absorption in order to determine the new form for equation (1) appears impossibly complex.

Stability of Evaporated Films

It has often been assumed that metal films condensed at a low temperature (−183° or −195° C.) are stable after warming several times to around room temperature. The recent work of Klemperer and Stone[1] and Rosenberg[2] on evaporated nickel and cleaved germanium surfaces respectively suggests that physical changes occur at the surface during oxygen chemisorption. Harrison and Morrison[3] have postulated that similar changes occur when sodium chloride surfaces, formed by evaporation, are kept *in vacuo* at room temperature. These physical changes result in a decrease in area of the respective surfaces, Klemperer, Stone and Rosenberg detecting the process by the physical adsorption of krypton, Harrison and Morrison deducing it from results obtained by an isotopic exchange technique.

In this Laboratory a fundamental study of the interaction of oxygen with iron surfaces is being carried out, and it is therefore important to determine whether this change in surface area can occur with evaporated iron films after the usual warming and cooling process has been repeated several times.

Chemically 'clean' surfaces were prepared by evaporation in a high-vacuum greaseless apparatus. An iron film condensed at −195° C., of weight 6 mgm. and apparent area 130 cm.^{2}, was warmed several times to room temperature (with intermittent cooling to −195° C.) before starting adsorption experiments.

Krypton isotherms determined at −195° C. on a clean surface and on the same one having chemisorbed 220 × 10^{-3} cm.^{3} (S.T.P.) oxygen at an immeasurably fast rate at an equilibrium pressure of 10^{-5} mm. and 24° C. are shown in Fig. 1. (This quantity of oxygen is the maximum that the iron surface would adsorb in this manner; further oxygen uptake occurred at a measurable rate.) Using the theory in ref. 4, these isotherms correspond to krypton monolayers of 57 × 10^{-3} cm.^{3} (S.T.P.) and 33 × 10^{-3} cm.^{3} (S.T.P.) for the clean and oxidized surfaces respectively. The fast chemisorption of oxygen has thus resulted in a decrease of the surface area to 0·23 of its original value.

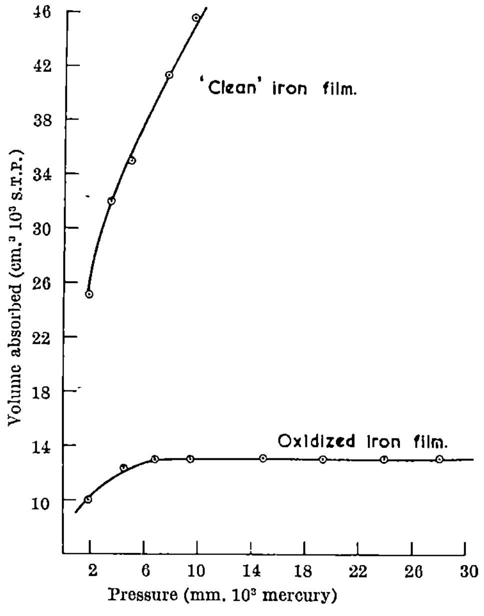

Fig. 1. Krypton isotherms at −195° C.

The effect of 'ageing' a clean iron film *in vacuo* at 24° C. was then considered. An iron surface, prepared as described above, was kept at a pressure less than 10^{-6} mm. at 24° C. and the surface area measured after various time-intervals. It was shown that the surface decreased in area with time. This effect is, however, of a smaller magnitude than that observed during oxygen chemisorption, the area decreasing to 0·72 of its original value in 20 hr.

It is evident that such changes in surface area must be taken into account in interpreting results with evaporated surfaces. A fuller account of this work will be given elsewhere. This communication is published by permission of the Director of the National Chemical Laboratory.

A Calorimeter for Determination of Heats of Wetting

For most problems connected with the properties of surfaces a need is felt for an apparatus which permits a rapid determination of the heats of adsorption. A suitable calorimeter was constructed, therefore, to determine the heat evolved when solid surfaces come into contact with different amounts of liquids. The calorimeter can determine heats of adsorption as low as 0·001 cal./gm. and the time of each determination is of the order of 30 min.

The apparatus consists essentially of a cell filled with an adsorbent, thermocouples placed in direct contact with the adsorbent, and a suitable jacketing arrangement. The cell is kept at a constant temperature and a liquid is allowed to flow through the cell at a constant rate. When the liquid comes into contact with the solid, a temperature rise is produced and measured by the thermocouples. The heat of adsorption of the liquid on the solid is evaluated by reproducing the temperature rise by passing a known current through a heater situated in the centre of the cell. Heats of replacement of one liquid by another liquid on a given adsorbent may be estimated by allowing a carrier liquid to flow through the cell at a constant rate and introducing into this liquid the second material.

In Fig. 1 a calorimeter with 13 thermocouples is shown. An ice bath encloses the cell containing adsorbent. A capillary jet is attached to the end of the separating funnel containing the carrier liquid and the bore of the jet controls its rate of flow. A small plug of cotton-wool retains the adsorbent in the cell. The hot junctions of the thermocouples are situated immediately above the plug and are sealed, by means of a casein glue, into the wall of the cell. The ends of the thermocouples are only slightly protruding from the wall and are in direct contact with the powdered solid. A coil of nichrome wire possessing a resistance of 10 ohms is situated in the centre of the cell. The coil is used to reproduce the effects taking place during adsorptions, by passing through it a small current from a source of constant known voltage, for a given length of time.

A glass tube is connected directly to the cell and extends to a special attachment which is used for introducing small quantities of unknown substances from a micrometer syringe, while a carrier liquid flows continuously through the apparatus. Enamelled copper and constantan wires (32 S.W.G.) are used for the thermocouples. The thermojunctions are made by twisting the bare ends of the wires together and brazing with the minimum amount of silver. The wires from the hot junctions pass out of the glass jacket, through holes in the rubber bung to the outside of the jacket, where the cold junctions come into direct contact with the ice. The cold

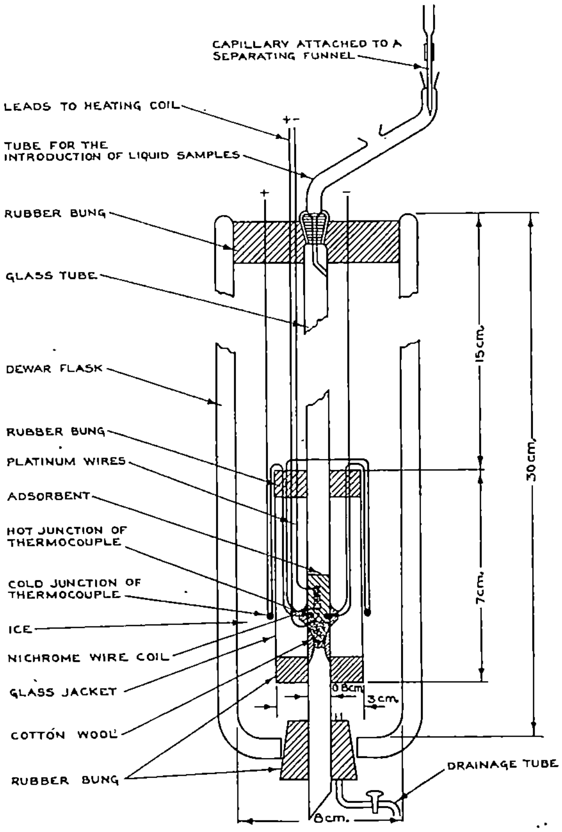

Fig. 1

junctions are held in position by a series of rubber bands. The ends of the two connecting copper leads are joined to either a galvanometer or a potentiometric recorder.

An illustration of the results that can be obtained with the calorimeter is given by the temperature rises produced by wetting of silica gel by a number of organic liquids. In Fig. 2 the temperature of the cell is plotted against the time, and the peaks shown represent the increases of temperature produced by the successive wetting of the adsorbent by *n*-decane, 1-dodecene, *m*-xylene, α-methylnaphthalene, *m*-cresol, *iso*propyl alcohol and acetone. In each case 0·05 ml. of a substance was injected into the carrier liquid consisting of *n*-heptane. (For acetone only 0·025 ml. was injected.) It is noteworthy that *n*-decane gives a measurable response when the carrier liquid is another paraffin, *n*-heptane. Substances of different chemical type give a much greater response.

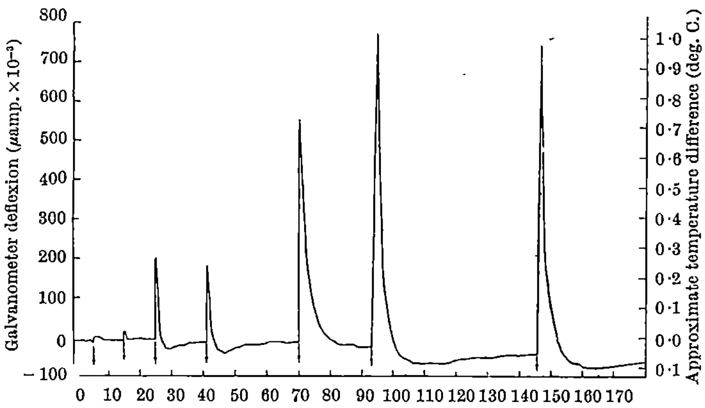

Fig. 2. Temperature rises produced by various substances. Peaks (indicated by arrows) from left to right: decane, 1-dodecene, *m*-xylene, α-methylnaphthalene, *m*-cresol, *iso*propyl alcohol, acetone

Capillary-tube Viscometry with Negligible Kinetic Energy Effects

The uncertainties associated with the kinetic energy correction in conventional capillary-tube viscometry result in considerable inaccuracy and inconvenience. These uncertainties arise from the dependence of the kinetic energy 'constant', B, on flow-rate and on the form of the capillary ends, B being defined by the equation:

$$\nu = Ct - B/t$$

where ν is the kinematic viscosity, t is the time of flow and C is the principal calibration constant. The significance of the kinetic energy term in the accurate measurement of the viscosity of liquids using capillary viscometers was emphasized at the recent symposium[1] arranged by the Institute of Petroleum and the British Society of Rheology.

In the course of work carried out during the past two years at the National Standards Laboratory, Sydney, capillary viscometers of both U-tube and Ubbelohde types have been developed in which the kinetic energy effect is entirely negligible. Since the viscometers are but little more difficult to construct than those employed in the usual standard procedures, as exemplified in B.S.S. 188 : 1957, they could with profit be adopted for those procedures.

The practical elimination of the kinetic effect is achieved by forming a gradual flare, generally a few centimetres long, at each end of the capillary tube. The flares may be so long as to run together at the centre of the tube, which then possesses no parallel part. Using viscometers with the capillary ends flared in this way, it has been found that the value of B is reduced to less than 0·02 of its value for otherwise similar conventional viscometers used at the normal flow-rates. In a series of measurements at higher flow-rates it was found that the kinetic energy effect could only be detected with certainty at flow-rates corresponding to Reynolds numbers exceeding three times the highest values encountered in conventional viscometry. At much higher flow-rates the value of B for the flared capillaries used in these experiments increased monotonically with Reynolds number, reaching, for example, about half the usual value at a Reynolds number of a thousand.

The long flare is readily produced by applying pneumatic pressure to a parallel capillary tube, with the end sealed, while it hangs in a temperature gradient in a furnace. A uniform temperature gradient is suitable.

A detailed account of this work has been submitted for publication elsewhere.

Temperature and Turbulence in Quiescent Prominences determined from Line-widths

Some years ago, one of us attempted to determine the kinetic temperature of atoms and a possible turbulence in some quiescent prominences[1]. Since at that time the different lines of a prominence had to be exposed one after the other and since only Hβ and D3 could be used for the purpose, it seemed desirable to make further observations of solar prominences with improved equipment[2].

The present observations were made with our tower telescope ($f = 24$ m.) using a Bausch and Lomb concave grating (radius of curvature 665 cm.). The prominences were guided on to the slit of the spectrograph (height of the slit 0·6 mm.) by using a Lyot Hα filter[3]. The following lines—arising with good approximation in an optically thin layer—could be exposed simultaneously : λ 8542 and (in some spectra) λ 8498 of Ca+, λ 5875 of He, λ 4340 and λ 3970 of H, the Balmer lines in the second order, the other lines in the first order. Since the molecular weight of calcium is forty times greater than that of hydrogen, the separation of temperature and turbulence is fairly certain. All line-widths have been corrected for the finite resolving power of the spectrograph.

Table 1 gives the results for ten quiescent prominences. The temperatures and the turbulent velocities are mean values computed according to the method of least squares, giving double weight to the widths of the Balmer lines. The different values given for one and the same prominence belong to different exposures. The scatter expresses, therefore, not only the uncertainty of the measurements but also local differences in temperature and turbulence within a prominence, since it was not always possible to place the same spot of the prominence on the slit of the spectrograph for all exposures.

The kinetic temperatures—significantly higher than the excitation temperatures derived earlier[1]—and the turbulence in quiescent prominences are probably of the same order of magnitude as in the lower chromosphere. A slight but significant negative correlation ($r = -0{\cdot}52$, $n = 39$) exists between kinetic temperature and turbulence. This correlation is somewhat more conspicuous if the H and He lines are treated separately ($r = -0{\cdot}64$, $n = 35$), and is absent if the He and Ca+ lines are treated separately. From a physical point of view the negative correlation is likely to be a pseudo-correlation, suggesting that the Balmer lines arise in a different layer of a prominence from the D3 line of He and the Ca+ lines.

A detailed discussion of our improved observations will appear shortly in the *Nachrichten der Akademie der Wissenschaften in Göttingen, Math.-Phys.-Klasse*.

Electron Spin Resonance in Carbons : a New Oxygen Effect

Ingram and Tapley[1] and Uebersfeld and Erb[2] have observed that electron spin resonance in certain carbons can be affected by oxygen. Austen and Ingram[3] showed that the electron spin resonance signal given by a carbon in vacuum may be (*a*) broadened, (*b*) reduced in total integrated intensity, by exposure to oxygen at room temperature. In both cases, it was found possible to restore the signal to the value it possessed in vacuum by outgassing the sample for a few minutes at room temperature.

Starch	—	$12·8 \times 10^{19}$	—	—
Decomposed carbons (oxidized carbons reheated in vacuum)				
Cellulose (to 550° C.)	860	$5·3 \times 10^{19}$	835	910
Sucrose (to 550° C.)	1,230	$12·8 \times 10^{19}$	1,020	930
Polydivinylbenzene (to 580° C.)	970	$13·5 \times 10^{19}$	1,680	1,740
Starch (to 570° C.)	2,270	$12·8 \times 10^{19}$	1,370	760

We have observed an oxygen effect with carbons which we believe to be quite distinct from that described by previous workers. In this case, oxidation of the carbon at more elevated temperatures produced a reduction in the total concentration of free radicals, which could not be restored by outgassing the sample at room temperature.

Carbons were prepared by heating cellulose, sucrose, starch, and pre-oxidized polydivinylbenzene in vacuum to 700° C. After cooling in vacuum, these carbons were oxidized by heating in air at a temperature in the region of 300–400° C.; details of the oxidation treatment are given in Table 1. After a preliminary outgassing for 24 hr. at room temperature, the oxidized carbons were reheated in vacuum. This treatment decomposed some of the surface oxide with the production of a volume of gas which, on analysis, proved to be a mixture of carbon monoxide and carbon dioxide.

The formation and decomposition of acid surface oxide[4] was followed by studying the sorption of sodium hydroxide by each of the carbons. 1 gm. of carbon was shaken for 24 hr. with 30 ml. of 0·26 *N* sodium hydroxide and the final concentration of alkali in the supernatant solution found by titration with dilute acid, care being taken to exclude atmospheric carbon dioxide. A specimen of the neutralized carbon was dried at 100° C. and examined as described below.

The electron spin resonance of the unoxidized, oxidized, neutralized and 'decomposed' carbons was examined using a standard X-band microwave spectrometer. All specimens were prepared for electron spin resonance measurements by outgassing at room temperature for 20 hr., heating at 200° C. for 1 hr. and finally sealing in vacuum. It seems certain, therefore, that the oxygen effect described by previous workers[1–3] was not occurring in these experiments.

In general, the unoxidized specimens possessed large electron spin resonance signals (Table 1). When oxidized, the samples showed a large increase in acidity, while the total concentration of free radicals was considerably reduced. By heating the oxidized sample in vacuum at about 550° C., some of the surface oxide was decomposed and the signal was partially restored. Neutralization of the oxidized material with sodium hydroxide also caused a partial recovery of the electron spin resonance signal.

We attribute the reduction in concentration of total free radicals on oxidation to the formation of surface oxide, as indicated by the increased acidity of the specimens. The partial recovery of the electron spin resonance signal on reheating the oxidized carbon provides further confirmation of the idea. The adsorbed oxygen appears to be more tightly bound than that encountered by Austen and Ingram, since it was not removed during the outgassing treatment but only at higher temperatures, as a mixture of carbon monoxide and carbon dioxide. It seems possible that, in the earlier work, the oxygen molecules were weakly adsorbed as a charge-transfer compound of the type described by Mulliken[5], whereas our results appear to be due to the formation of covalent oxides. The possibility is therefore raised that the electron spin resonance of carbons prepared from materials containing oxygen may be dependent, to some extent, on the proportion of oxygen retained by the structure during carbonization. The behaviour of sodium hydroxide in partially restoring the concentration of radicals of oxidized carbons is not yet fully understood, but further work is being carried out to clarify this effect.

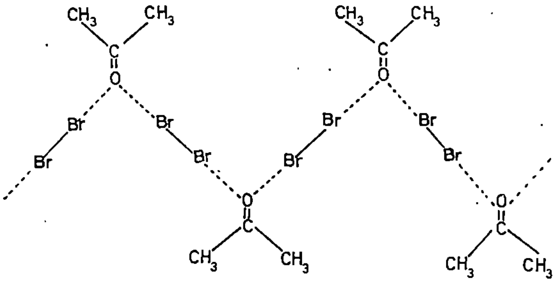
Halogen-Molecule Bridges in Solid Addition Compounds

One very striking result obtained from X-ray work on solid addition compounds in which halogen molecules act as electron acceptors is the fact that both halogen atoms of a particular Hal_2 molecule may simultaneously be linked to donor molecules. Thus, in the 1 : 1 compounds formed by 1,4-dioxan and bromine (or iodine) endless chains are present which are built up of alternating dioxan and halogen molecules and containing linear O—*Hal*—*Hal*—O arrangements[1]. Moreover, in the solid 1 : 1 compound formed by benzene and bromine, straight chains of alternating benzene and bromine molecules have been established[2]; the benzene-ring planes are parallel and the bromine molecules symmetrically arranged on the common chief axis of the benzene rings. Until quite recently it was uncertain whether more than one single halogen-molecule bridge could actually start from one particular electron donor atom. In the case of oxygen and other donor atoms possessing more than one lone electron pair such an arrangement would not appear to be impossible.

The 1 : 1 compound between acetone and bromine actually affords an example of this kind. According to new results the crystals of this compound contain endless chains of the type :



Here, both lone electron pairs belonging to a particular keto oxygen atom evidently take part in halogen bond formation. The keto carbons and oxygens and the bromine atoms belonging to the same chain are coplanar and the O—Br—Br—O arrangements strictly linear. The methyl carbons do not appear to lie exactly in the plane of the other atoms of the chain. This is probably so because otherwise the distances between methyl carbons and bromine atoms would be energetically unfavourable. The Br—Br distance appears to be very little different from the distance observed in the free molecule (2·28 A.). The O—Br distance was found to be 2·82 A. and the Br—O—Br angle nearly 110°. Details of the structure determination will be published elsewhere. The space group is $C2/c$ and the lattice parameters are as follows :

$a = 7{\cdot}12$ A. $b = 7{\cdot}48$ A. $c = 12{\cdot}90$ A. $\beta = 111{\cdot}5°$

The unit cell contains four molecules.

Boron-10 Abundance in Nature

The most reliable values for the isotopic abundance of boron-10 in naturally occurring minerals have been derived from mass spectrometer measurements. Results quoted by different workers, however, range from 18·4 to 19·9 per cent boron-10, and it is not difficult to find possible causes for the variation. Most of the measurements have been made with boron trifluoride, which is a difficult compound to handle in a mass spectrometer, since memory effects and interference from impurities can give very erratic and incorrect results ; even when there are no errors of this kind, it is still possible for results to be biased by mass discriminations in the mass spectrometer, and no reported attempts have been made to standardize the results in any way. Insufficient care when preparing samples from the natural minerals could also cause errors arising from discrimination with respect to one isotope. The possibility of variation of the abundance of boron-10 in Nature has been investigated by Parwel *et al.*[1], who examined a large number of minerals and found only a slight difference for boron obtained from sea water.

Among the more recently reported results, Osbergaus[2] quotes a constant value of 19·6 per cent boron-10 for a small number of minerals examined. Panchenkov and Moissev[3] quote 18·4 per cent boron-10 for (presumably industrially prepared) boron trifluoride. Kilpatrick *et al.*[4] claim to have eliminated their mass discriminations and quote 18·8 per cent boron-10 for industrially prepared boron trifluoride.

In order to make a check on mass spectrometer discriminations and to obtain a more accurate figure for the natural abundance of boron-10, we have prepared standard samples of boron trifluoride with known isotopic content. Primary standards were prepared by blending enriched and depleted boron trifluoride in known proportions, and these were compared with bulk secondary standards using a mass spectrometer. We later compared the appropriate secondary standard with a sample of boron trifluoride which had been carefully prepared from naturally occurring boron. This sample has been shown by Parwel *et al.*[1] to contain boron with the same isotopic composition as that obtained from all the other minerals they examined ; we are indebted to H. von Ubisch of A. B. Atomenergi, Stockholm, for supplying this sample. Our results show that the mass spectrometer discriminations, expressed as a fraction of the isotope ratio, are the same for both enriched and natural boron trifluoride, as might be expected. The naturally occurring boron sample was found to contain (19·3 ± 0·1) per cent of boron-10.

A more detailed account of the preparation of the isotopic standards and of the mass spectrometer measurements will be published elsewhere.

Surface Concentrations of Manganese Nodules

Manganese nodules were investigated during the Downwind Expedition, a part of the International Geophysical Year programme of the Scripps Institution of Oceanography of the University of California. Attempts were made to collect bottom photographs, cores and dredge hauls in the same areas, to measure the distribution at the surface and in depth, and to obtain large samples for physical and chemical analysis.

Although nodules were sampled and photographed in various places along the expedition track between California, Tahiti and South America, the greatest concentration was found on the red clay bottom deeper than about 4 km. in the south-western Pacific Basin. Nodules had been discovered in the basin by the *Challenger* eighty-five years before. The two ships of the expedition followed the track of

the *Challenger* and explored a narrow band about 2,700 km. long in a south-easterly direction from latitude 25° S. to 45° S. in the eastern part of the basin. Two bottom photographs, twenty-three gravity cores and two dredge hauls were obtained. Photographs (Fig. 1) indicate that about a quarter to a half of the sea floor in this basin is covered with manganese nodules and that the weight per unit area is about 1–4 gm. cm.$^{-2}$ (Table 1). The surface concentration was determined by standard statistical procedures. Density of the nodules is about 2·0 gm. cm.$^{-3}$. The scale of the photographs is known, and the volume of the nodules can be estimated because the smaller nodules are roughly spherical and the lengths of their shadows give a scale for measuring the thickness of slab-shaped nodules. The sizes computed agree reasonably closely with the sizes dredged.

The group of cores gives less definite evidence of the fraction of the bottom covered with nodules in the south-western Pacific Basin but it provides a means of interpolation between the widely separated camera stations. Some twenty-three gravity cores contained samples as follows: six sediment but no nodules; four manganese oxide fragments in core nose; four small nodules only; nine sediment and nodules including eight with nodules at surface. Omitting one smaller core for uniformity, each of twenty-two cores has a cross-sectional area of 18 cm.^{2}. The four cores with manganese oxide fragments may be assumed to be hits on large nodules each with an area of 18 cm.^{2}. The thirteen cores with nodules alone or nodules and sediment have fifteen nodules at the surface with an average diameter of approximately 1 cm. These figures indicate one-fifth of the bottom is covered with nodules along the transverse. Consequently, the average coverage of nodules indicated by coring is about the same as the minimum shown on photographs. The average coverage from coring would be greater if four other coring attempts were counted as hits on large nodules. On each of these a ball-break indicated that the cores hit bottom, but no sample of any kind was obtained in the cores. However, nodules were indicated by black streaks and scratches not only on corers but on the camera and temperature probe. Similar streaks on equipment were observed in this area during the *Challenger* Expedition[1] and interpreted as indicating very abundant nodules.

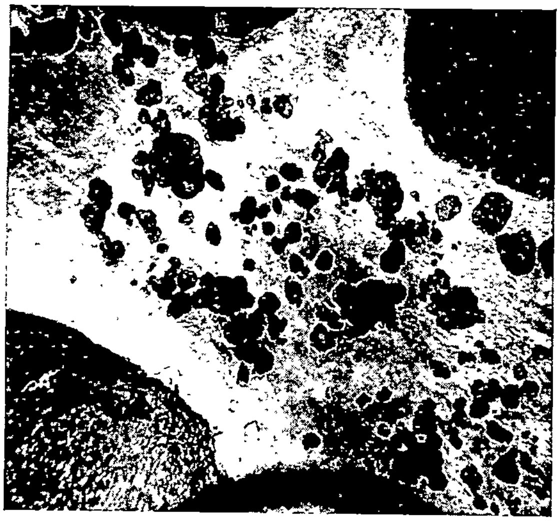

Fig. 1. Photo *DWP*-11. Area about 6 m.^{2}

Nodules are not limited to the surface of the sea bottom. Of fifteen cores that penetrated deeper than 11 cm., three contained nodules at depths of 8–11 cm. Of thirteen cores penetrating to 72 cm., six had nodules 48–72 cm. below the surface. No other nodules have been found in a maximum penetration of 140 cm. One core penetrated to approximately 47–50 cm. where a small nodule was lodged in the core catcher. This is the only core which ceased penetrating when it reached one of the nodule-rich zones. Consequently, there is no positive indication that large nodules (which would stop the corer) occur anywhere except at the surface. Moreover, some of the cores may have hit the bottom more than once, with the result that some nodules that appear to be buried in sediment were actually at the surface.

Manganese nodules are a potential resource so that an estimate of the amount in the south-western Pacific Basin may be of interest. The U.S.S. *Enterprise* took a latitudinal line of samples by sounding lead across the basin at about 50° S. Several records of 'black specks' and one 'black stone' may indicate manganese nodules or fragments. No other samples are available, and it is only an assumption that the concentration of nodules found along the Downwind track is characteristic of the whole basin. The basin deeper than 4 km. has an area of roughly 10^{7} km.^{2}. If the concentration of nodules is uniform at 1 gm. cm.$^{-2}$, the total weight of the surface deposit is 10^{17} gm. Average chemical analyses of Pacific nodules suggest that iron and manganese are present in the deposit in amounts of 10^{16} gm., and cobalt, copper and nickel and rare earths each amount to 10^{15} gm.

Dredge hauls and cores show that nodules are distributed within perhaps 5×10^{7} km.^{2} of the Pacific Basin, but little is known about the concentration per unit area. Photograph *DWP*-8 in French Polynesia indicates that nodules cover about a quarter of the surface, but the photograph is oblique and subject to greater errors of interpretation than photographs *DWP*-10 and -11 (Fig. 1). Similar concentrations are suggested by photographs in other areas, but the nodules are partially covered with sediment and only rough estimates are justified. Nevertheless, the scanty evidence available suggests that manganese nodules cover a considerable fraction of the deep sea floor in many parts of the Pacific Basin. This circumstance presents a puzzle, because the upward growth of nodules may be one or two orders of magnitude slower than commonly accepted average deposition rates of sediment in the deep sea[2].

Diffusion of Zinc in Gallium Arsenide

ZINC is an acceptor impurity in gallium arsenide with small ionization energy. If it is the predominant impurity and is present in low enough concentration, then the Fermi-level will lie above the zinc-levels and the zinc atoms will nearly all be ionized, that is, they will have accepted an electron. As the zinc concentration increases, the Fermi-level will descend into the valence band and the proportion of ionized atoms becomes small. Since the speed of diffusion of an atom will be different in its ionized and in its un-ionized state the diffusion coefficient will depend upon concentration.

The conditions under which one might observe this effect are as follows. We define a critical concentration N_0 of zinc atoms above which most of them will not be ionized, and below which most of them will be. Then we require the surface concentration to be greater than N_0 and the intrinsic number of holes and electrons to be small. These conditions can easily be satisfied for zinc diffusing into gallium arsenide at 1,000° C. We have worked out the theory of this system and in Fig. 1 we show a theoretical curve of impurity concentration as a function of distance into a specimen when the diffusion is into a semi-infinite block with constant surface concentration of impurity. Also shown are some experimental points obtained by a radioactive tracer method. The agreement between theory and experiment is seen to be quite good. The most interesting feature of the curve is the change in slope when the concentration is equal to N_0, giving a very steep diffusion front, and this effect will obviously be of importance in design problems.

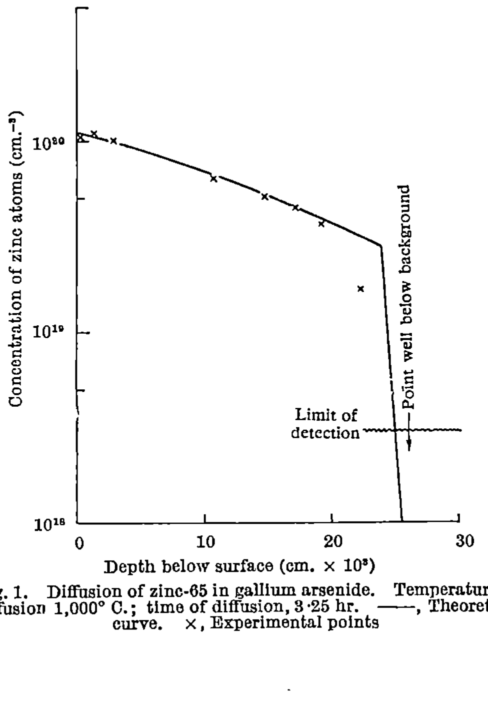

Fig. 1. Diffusion of zinc-65 in gallium arsenide. Temperature of diffusion 1,000° C.; time of diffusion, 3·25 hr. ——, Theoretical curve. ×, Experimental points

Two further points emerge which may be stressed. First, we can find from our analysis of the experimental results the diffusion coefficient of zinc in both the ionized and the un-ionized states. Preliminary measurements show that at 1,000° C. the diffusion coefficient of un-ionized zinc is about thirty times greater than that of ionized zinc. This is reasonable, since when the zinc has accepted an electron it is presumably more tightly bound and is also larger. We hope to find the two coefficients as a function of temperature in order to compare the activation energies. Secondly, the effects are particularly pronounced in the zinc–gallium arsenide system because the conditions enunciated above are well satisfied, but they may occur in other systems to a lesser degree and produce apparent anomalies. For example, it is quite possible to have an apparently normal concentration – depth curve which when extrapolated to the surface yields a value for the surface concentration considerably different from the true value. Full details of the theory and experiments and a discussion of these possibilities will be published elsewhere.

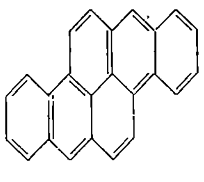
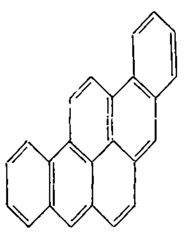
Presence of 3 : 4-8 : 9-Dibenzpyrene in Coal-Tar

ALTHOUGH several carcinogenic hydrocarbons of varied potency have been isolated from coal-tar, including 1 : 2-5 : 6-dibenzanthracene, 3 : 4-benzpyrene[1], and 1 : 12-benzperylene[2], it is known that the presence of such substances is not sufficient to account for both the qualitative and the quantitative carcinogenicity of coal-tar itself. This consideration warranted the search for further carcinogens in coal-tar, particularly in pitch fractions containing the more condensed aromatic hydrocarbons, and especially in view of the considerable carcinogenic activity of several hexacyclic hydrocarbons such as 3 : 4-8 : 9-(I)[3] and 3 : 4-9 : 10-dibenzpyrene (II)[4]. Schoental[5] has recently reported the presence of (II) in a carcinogenic fraction of coal-tar, and this prompted the present report of the isolation of another potent carcinogen, 3 : 4-8 : 9-dibenzpyrene, from similar material. This hydrocarbon, which was isolated in small amounts by the usual fractionation and chromatographic methods, from the fractions boiling above 500° C. of various samples of coal-tar pitch,



(I)



(II)

was identified by direct comparison of melting point and ultra-violet and fluorescence spectra with those of an authentic sample prepared by zinc dust reduction of 3 : 4-8 : 9-dibenzpyrene-5 : 10-quinone[6].

3 : 4-8 : 9-Dibenzpyrene is a carcinogen of particular interest, not only because it has been detected among the constituents of tar from tobacco smoke[7] but also because it has been shown to possess considerable sarcoma-producing activity in male mice of strain XVII of this Institute, whereas female animals of the same strain are far less susceptible[8].

A Simple, Rapid Method for Circular Paper Chromatography

I have recently developed in our laboratory the following method for the circular development of a large paper disk which has the advantages of (*a*) rapidity, requiring no more than two and a half hours for a satisfactory separation of sugars and amino-acids, and (*b*) simplicity, as it does not need the various devices of other workers[1,2].

Whatman paper disks 26 cm. in diameter are used. In the centre of the paper a circle 1·5 cm. in diameter is drawn with a pencil. Four to eight cuts, depending upon the number of the samples which will be examined, are made from the periphery up to the centre (Fig. 1). The resulting tips of the triangular areas are bent downward. Each spot is applied on the periphery of the circle, between two adjacent cuts. The solvent is placed in a small vessel which is supported on a glass stand in a glass desiccator 25 cm. in diameter, so that the rim of the vessel is approximately 1 cm. below the rim of the desiccator. Then the tips of the triangular spaces are dipped into the solvent and the desiccator is closed. The front develops as a circle, provided that the desiccator is levelled carefully.

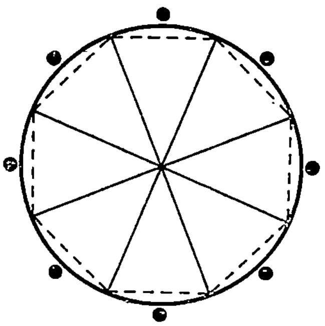

Fig. 1. Diagram showing the cutting and bending of the paper. The solid lines represent the cuts. The broken lines the places where the paper is bent down. The dots represent the spots

Further details of this method will be published elsewhere.

Configuration of N-acetylneuraminic Acid

Recently, Comb and Roseman[1] observed that N-acetyl-*d*-mannosamine and not N-acetyl-*d*-glucosamine was a substrate for the enzyme synthesizing N-acetylneuraminic acid (nanaldolase) isolated from *Clostridium perfringens*. These results seem to be in conflict with the synthesis of N-acetylneuramic acid from N-acetyl-*d*-glucosamine as reported by Cornforth, Firth and Gottschalk[2]. The observations of Comb and Roseman suggest that N-acetyl-*d*-mannosamine should be the starting product for the synthesis of N-acetylneuraminic acid.

From the reaction mixture of a condensation between N-acetyl-*d*-mannosamine and oxaloacetic acid in aqueous alkaline solution (*p*H 11) at room temperature we isolated an acidic crystalline substance. This acid proved to be identical with N-acetylneuraminic acid isolated from a similar reaction between N-acetyl-*d*-glucosamine and oxaloacetic acid[2]. In both cases the yield was only 1–2 per cent. Variation of the conditions of the reactions and of the relative amount of the reactants did not improve the yield.

Both acids had the same equivalent weight, optical rotation (in water), R_F value (0·13) on Whatman No. 1 paper (descending; butanol/pyridine/water 6 : 4 : 3), intensity of the colour produced with Ehrlich's reagent (measured at 565 mμ), infra-red spectrum in compressed potassium bromide and X-ray powder diffraction pattern (copper K_α). Mr. Boschman of this laboratory found that both substances inhibited influenza virus enzyme to the same degree[3].

The isolation of identical products from the reaction of N-acetyl-*d*-glucosamine and N-acetyl-*d*-mannosamine with oxaloacetic acid appeared to be due to the epimerization of the two amino-sugars under the conditions of the reaction. Aqueous solutions of both amino-sugars (concentration 75 mgm./ml., that is, the same concentration as used in the condensation reaction) were brought to *p*H 11. After standing some time at room temperature the solutions were neutralized with 'Dowex' 50. Samples were run on borate-treated paper with the butanol, pyridine/water (6 : 4 : 3) mixture[4]. Colouring the chromatograms with Ehrlich's reagent after pretreatment with alkali revealed that both solutions contained N-acetyl-*d*-mannosamine as well as N-acetyl-*d*-glucosamine. The epimerization attained equilibrium after 10 hr. as was shown by a determination of the amount of amino-sugar in eluates of the individual spots. At equilibrium the ratio of N-acetyl-*d*-glucosamine to N-acetyl-*d*-mannosamine was 2·2 to 1. After 48 hr., the total amount of amino-sugar was about 75 per cent of the original. Recently, Comb and Roseman[5] have also reported the epimerization of N-acetyl-*d*-glucosamine in aqueous solution at *p*H 11.

These results indicate that the opinion of Cornforth, Firth and Gottschalk[2] that their synthesis confirms Gottschalk's[6] proposal of the configuration of N-acetylneuraminic acid is not wholly justified. Further, we conclude that the isolation of N-acetyl-*d*-glucosamine after an alkaline degradation of N-acetylneuraminic acid as reported by Kuhn and Brossmer[7] and by Zilliken and Glick[8] can be ascribed to the rapid epimerization of N-acetyl-*d*-mannosamine formed originally. This means that the isolation of N-acetyl-*d*-glucosamine can no longer be taken as a proof of the configuration at C_6 of N-acetylneuraminic acid[7]. Our experiments lend support to the results of Comb and Roseman[1]. This implies that the configuration at carbon atoms 5–8 of N-acetylneuraminic acid is the same as the configuration at carbon atoms 2–5 of N-acetyl-*d*-mannosamine.

We are indebted to Mr. A. H. Bierens and Mr. J. Schut for their assistance.

Note added in proof. R. Kuhn and R. Brossmer (*Ann.*, 616, 221; 1958) have re-investigated the degradation of N-acetylneuraminic acid with pyridine and nickel acetate[7]. They now find that N-acetyl-*d*-mannosamine is formed primarily and that this rapidly epimerizes to N-acetyl-*d*-glucosamine.

3-Ethoxy-4-hydroxybenzoic Acid in Human Urine

In a recent communication[1] an increased excretion of vanillic acid during the stress of motor-rally driving was reported. The 1958 Royal Automobile Club rally offered an opportunity to confirm this finding, and three samples of urine were collected from each of two subjects during the third and fourth days. This was after a considerably longer period of stress than had been experienced in the previous experiment and was determined by the accessibility of the subjects. Acid-hydrolysed urines were examined by the method used previously[2] and both hydrolysed and unhydrolysed urines by a modification of the method of Armstrong *et al.*[3]. In all the samples, vanillic acid was detected only in perfectly normal amount.

However, chromatograms of the final sample from one of the subjects showed the presence in comparatively large quantity, particularly after hydrolysis, of an unusual substance which had previously been detected in four of the ten urines in the first experiment, although in comparable amount in only one of them. Further, reference to chromatograms (prepared some years ago by P. S.) of urines from subjects rendered anoxic by decompression for two hours to a pressure equivalent to an altitude of 14,000 ft. showed that a similar substance had been recorded as present in small amount in six of twenty-three such urines. In thirty-eight normal urines collected over a similar period of time (approximately 9.30–11.30 a.m.) from the same subjects (fifteen normals were duplicated) the compound had been detected only twice. Because no particular attention was paid at the time to this then rather obscure substance the numbers quoted above should be regarded with some reservation, since it is possible that trace amounts might have escaped notice on some chromatograms on which its presence had not been recorded.

The new compound was indistinguishable from vanillic acid in its behaviour towards diazotized sulphanilic acid or *p*-nitroaniline, Folin and Ciocalteu's reagent or 2 : 6-dichloroquinone chloroimide[2], but had higher R_F values in all organic solvents tried. These properties suggested a homologue of vanillic acid, and the substance was readily shown to be excreted following ingestion of ethyl vanillin; it has now proved to be chromatographically identical with 3-ethoxy-4-hydroxybenzoic (ethyl vanillic) acid.

Present evidence suggests ethyl vanillic acid may be detected in normal urines, though rarely in more than trace amounts, rather more frequently than is suggested by the anoxia controls mentioned above, particularly in samples collected at different times of the day. One urine collected after lunch contained the substance in large quantity. Inquiry revealed that the subject in question had, during the previous twenty-four hours, consumed a surprising variety of sweets, but no difficulty was encountered in demonstrating the origin of ethyl vanillic acid to be a well-known confection which evidently contains much ethyl vanillin.

From the two driving-stress experiments, urines were collected from two of the subjects, co-drivers, on five occasions, in each case over similar periods of time. On two occasions nothing of interest was found, but the excretions of vanillic and ethyl vanillic acids in the remaining three pairs of urines are compared in Table 1. The average normal excretion-rate for vanillic acid is about 85 μgm./hr. while ethyl vanillic acid is usually present only in trace amounts. Considerable differences between the subjects in the rates of excretion of at least one of the substances are evident on two of the occasions. Since it is known that these two subjects consumed virtually identical meals throughout, and taking into account our present knowledge of dietary sources of the two compounds, we find it difficult to escape the conclusion that both have an endogenous origin responsible for their increase during stress. The alternative possibility that some substance—which

Table 1. RATES OF EXCRETION OF VANILLIC AND ETHYL VANILLIC ACIDS BY TWO SUBJECTS UNDER STRESS

A. M. H. B.		30	0

must have been eaten by both subjects—can give sometimes vanillic acid, sometimes ethyl vanillic acid, and on other occasions yield no detectable metabolite, seems rather remote.

It is now clear that any conclusion that vanillic and ethyl vanillic acids are metabolites of adrenaline or other catechol of endogenous origin must await the demonstration that biological ethylation of a catechol hydroxyl group is possible, as an alternative to methylation, in the human subject. Work at present on hand indicates strongly that this is so, but results so far have been insufficiently impressive and too erratic to merit publication at this stage.

We wish to thank the Director-General of Medical Services, Royal Air Force, for permission to publish this work, which will be presented in more detail elsewhere, and Dr. A. M. H. Bennett for his continued co-operation in the collection of urines.

Purkinje and Ventricular Membrane Resistances during the Rising Phase of the Action Potential

Using double-barrelled micro-electrodes, one barrel for recording the other for passing current, it has been found possible to observe the effects of hyper- and de-polarizing currents on the membrane behaviour of actively beating heart muscle.

An isolated preparation of rabbit right ventricle was driven at a constant rate (approximately 3/sec.) via external electrodes. Purkinje fibres were distinguished by their characteristic action potential and appeared to be localized to the endocardial surface in a sparse network of pale tissue bands similar to those described by Purkinje[1]. Rectangular pulses of current of 100 msec. duration were applied via one barrel of the micro-electrode 80 msec. before the onset of every fourth propagated action potential. Because of the proximity of the two barrels and the relatively high currents required (10^{-8}–10^{-6} amp.) it was not possible to compensate entirely for the artefacts which appeared at the recording electrode, and thus direct determination of the changes in membrane resting potential during the passage of a current pulse was not possible. However, the technique did permit the following measurements to be made: the maximum amplitude of the normal action potential, E_n; the maximum amplitude of the action potential occurring during current flow, E_c; and the applied current, I.

Assuming the current produced no change in membrane behaviour, the following would hold:

$$\frac{dE_c}{dI} = R_r - R_d \qquad (1)$$

where R_r is the polarization resistance in the resting state, R_d is the polarization resistance at the crest of the rising phase and E_c is the difference between the altered resting potential and the potential at the crest of the rising phase. Or, assuming R_r and R_d are constant:

$$E_c = IR_r - IR_d + E_n \qquad (2)$$

Weidmann[2] has shown that in Purkinje fibres of the kid the ratio R_r/R_d is greater than 50, so that the term R_d could be neglected.

A typical relationship between I and E_c in a Purkinje fibre is shown in Fig. 1. There is some variation among these fibres; but all exhibit a curve, straight for values of E_c above 90–100 mV. and curved for lower values. In the former, the slope (dE_c/dI) equals R_r, whereas the steepening in the latter is the result of the additional effect of current on the activity of the sodium-carrying system[3], which, in our experiments, appears maximal at 90–100 mV.

In ventricular fibres, when positive and low negative currents are applied, the slope dE_c/dI varies widely from fibre to fibre. It is generally low and sometimes negative in value. This implies that R_d in equation (1) is of the same order as, and sometimes greater than, R_r. With negative currents greater than a certain value dE_c/dI yields predictable values for R_r 2–3 times smaller than for Purkinje fibres. During this phase R_d is now obviously much smaller than R_r. However, the plot of the amplitude of the action potential 2 msec. after the crest (shown in Fig. 1 by an interrupted line) has a negative slope indicating that the membrane resistance at this time is higher than R_r.

Thus the resistance at the crest of the ventricular action potential is normally of the same order as the resting resistance; whereas in Purkinje fibres the resistance at the crest is much lower, indicating that in ventricular fibres, if there is a sodium-carrying mechanism its activity has normally ceased well before the maximum height of the action potential is reached. This could explain the fact that: (1) the amplitude of the action potential of ventricular fibres (contrary to that of Purkinje) does not decline with reduction in external sodium concentration in the manner predicted by the sodium theory[4-6], and (2) in ventricular

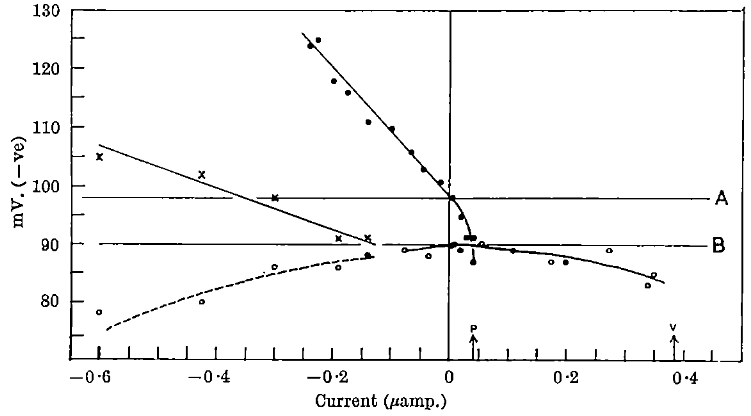

Fig. 1. Effect of current on the amplitudes of Purkinje and ventricular action potentials. Ordinate: action potential amplitude, E_c. Abscissa: current applied via stimulating barrel, +ve; depolarizing: −ve; hyperpolarizing. ●——●, Purkinje action potential; ○——○, ventricular action potential with positive and low negative currents; ×——×, ventricular action potential with high negative current; ○- - -○, ventricular action potential 2 msec. after the crest. *A* and *B* represent the normal amplitudes of Purkinje and ventricular action potentials respectively (that is, in the absence of applied current). *P* and *V* indicate Purkinje and ventricular threshold currents. In this particular experiment the polarization resistances (R_r) of the Purkinje and ventricular fibres were 100 k.ohm and 35 k.ohm respectively

fibres exposed to quinidine the maximum rate of rise of the action potential declines without a concurrent reduction in the amplitude[7].

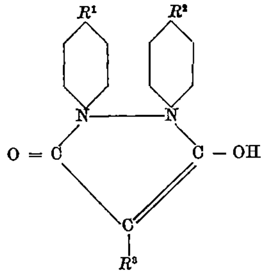
Relationship between pK_a and Uricosuric Activity in Phenylbutazone Analogues

DRUGS which increase the urinary excretion of uric acid are of considerable value in the treatment of gout. Although it is fairly well established that these agents act by interfering with the reabsorption of uric acid by the renal tubular cells, the structural features required for this activity have not been defined. In the course of studies with one such drug, phenylbutazone, a relationship between chemical structure and uricosuric activity was noted. It was found that modifications in phenylbutazone, resulting in increased acidity of the molecule, are associated with enhanced uricosuric activity. However, changes which decrease the acidity of the drug are accompanied by loss of this activity.

In Table 1 are given the pK_a, relative uricosuric activity and biological half-life of a variety of analogues having modifications either in the benzene rings or the butyl side chain of phenylbutazone. The pK_a values were determined in dilute aqueous solutions by a method based on the differences in ultra-violet absorption of the ionized and un-ionized forms of the compounds[1]. The relative uricosuric potency of each compound is expressed in terms of the intravenous dosage required in gouty subjects to elicit a 100 per cent increase in the clearance ratio $C_{\text{uric acid}}/C_{\text{inulin}}$. The biological half-life of each drug was calculated from their rate of disappearance from plasma after single 600–800 mgm. intravenous doses.

In Table 1 the various analogues are arranged in order of increasing acid strength. The *iso*propyl analogue (*G*–13838) and the *p*-dimethyl analogue (*G*–15235), the weakest acids in the series, had no detectable uricosuric effect in intravenous doses of 1,200 mgm. Phenylbutazone and *G*–27202 required 800–1,000 mgm. intravenous doses to elicit a 100 per cent change in uric acid clearance whereas *G*–28231

Table 1. pK_a AND URICOSURIC ACTIVITY OF PHENYLBUTAZONE ANALOGUES



Compound	R^1	R^2	R^3	pKa	Dose of drug for uricosuric effect (mgm.)*	Half-life (hr.)
G–13838	H	H		5·5	No effect with 1,200	72
G–15235	CH_3	CH_3	$CH_2CH_2CH_2CH_3$	4·9	No effect with 1,200	48
G–27202†	OH	H	$CH_2CH_2CH_2CH_3$	4·7	800–1,000	72
Phenylbutazone	H	H	$CH_2CH_2CH_2CH_3$	4·5	800–1,000	72
G–28231†	H	H	$CH_2CH_2\overset{OH}{\overset{\mid}{C}}HCH_3$	4·0	150–300	8
G–25671	H	H		3·9	150–300	3
G–28234	NO_2	H	$CH_2CH_2CH_2CH_3$	3·2	30–100	36
G–28315	H	H		2·8	30–70	3
G-32567	$\overset{O}{\overset{\Vert}{\underset{\underset{O}{\Vert}}{S}}}—CH_3$	$\overset{O}{\overset{\Vert}{\underset{\underset{O}{\Vert}}{S}}}—CH_3$	$CH_2CH_2CH_2CH_3$	2·7	100–150	1
G–30249	OH	H		2·0	30–70	3

* The intravenous dose required to elicit a 100 per cent increase in $C_{\text{uric acid}}/C_{\text{inulin}}$. The compounds were administered to gouty subjects by slow sustained infusion as described previously (refs. 2 and 3).

† *G*–27202 and *G*–28231 are metabolites of phenylbutazone in man (ref. 4).

and *G*–25671 produced this effect in doses ranging from 150 to 300 mgm. However, *G*–28315 and *G*–30249, two of the strongest acids, were active in doses as low as 30 mgm. Further experiments were carried out to determine the maximum uricosuric effect produced by the rapid injection of a single large dose of drug. For example, the rapid injection of 800–1,000 mgm. of either phenylbutazone or *G*–27202 increased the ratio $C_{\text{uric acid}}/C_{\text{inulin}}$ two- to three-fold, whereas the injection of 400 mgm. doses of either *G*–28315 or *G*–28234 increased the clearance ratio seven- to eight-fold. In addition, the oral administration of 800 mgm. doses of phenylbutazone and *G*–27202 produced about a 30 per cent increase in the daily excretion of uric acid over the control values, whereas the same dose of *G*–28315 and *G*–28234 produced about a 125 per cent increase.

The values obtained for the half-life of the various analogues rule out the possibility that the weakly uricosuric analogues may be metabolized or excreted too rapidly to achieve effective plasma levels. The compounds which had the most potent uricosuric effect, such as *G*–28315 and *G*–30249, actually disappeared at a considerably more rapid rate (half-life 3 hr.) than phenylbutazone, *G*–27202, *G*–15235 and *G*–13838 (half-life 2–3 days). The larger dose of *G*–32567 required to produce the uricosuric effect than that needed for *G*–28315 and *G*–28234 may be due to its extremely rapid disappearance (half-life 1 hr.).

The potent uricosuric activity of the highly acidic phenylbutazone analogues indicates that these drugs act in the ionic form to block the reabsorption of uric acid by the renal tubule cells, thus furnishing a possible clue to the still obscure nature of the transport mechanisms involved. The demonstration that uricosuric activity in the phenylbutazone series is related to the pK_a, has proved of considerable aid in searching for new uricosuric drugs. One such drug, *G*–28315, has already been found to be useful clinically as a potent uricosuric agent in treatment of gout[2,5,6].

We are grateful to Dr. Franz Haefliger and his colleagues of Geigy Pharmaceuticals, Basle, Switzerland, for the synthesis of the various phenylbutazone analogues used in this study.

Decay of Immediate Memory with Age

Current theory tends to emphasize the importance of interference in forgetting and to minimize the role of time lapse in the decay of the memory trace. Conrad[1], however, has recently shown that the immediate recall of eight-digit numbers is better when the numbers are presented and reproduced by subjects at a fast rate than when they are presented and reproduced at a slow rate. He interprets this finding as indicating that simple decay of the memory trace is an important factor in the loss of immediate memory.

In the course of a more complex investigation of the relation between age and ability to retain for short- and long-term periods various classes of material, I tested two groups of subjects for their ability to retain eight-digit numbers when presented and reproduced at different rates. Group *A* consisted of 26 teachers, aged 18–29, drawn from different regions of Canada. Group *B* consisted of 26 teachers, aged 30–55, also drawn from different regions of Canada, and matched as closely as possible with Group *A* in general background, marks on university summer-school courses, and tests of remembering.

The results confirmed Conrad's finding that immediate recall is better when the numbers are presented and reproduced by subjects at a fast rate (120 digits per min.) than when they are presented and reproduced at a slow rate (40 digits per min.). The mean fraction of digits recalled at the slow rate was 0·475, and at the fast rate 0·543. These scores are both better than those reported by Conrad, but the samples in the present experiment are probably drawn from populations of higher intelligence, and the rates of presentation are slightly faster than in Conrad's experiment, both factors being likely to improve the scores on an immediate memory task.

Analysis of the results shows that there is no significant difference between the two groups in the proportion of digits recalled at the fast rate, but that there is a significant difference between the two groups ($P = 0{\cdot}05$) in the proportion of digits recalled at the slower rate. The actual figures are given in Table 1.

Table 1

Group	Proportion of digits recalled	
	Slow rate	Fast rate
A	0·51	0·575
B	0·37	0·58

If Conrad's technique is an adequate measure of the decay factor in immediate memory, and if the present finding is confirmed by further research, it appears that the span of immediate memory is the same for the two age groups, but that the rate of decay of immediate memory tends to increase with age.

This study was carried out while I was in receipt of a grant from the Department of Veterans' Affairs, Ottawa. Full details of the completed study will be published elsewhere. My thanks are due to Dr. J. M. Blackburn for his interest and encouragement.

Comparison of the Tendency to cling to Glass and Hæmagglutination produced in Erythrocyte Suspensions by Ferric Chloride and by Influenza Virus

In a recent publication[1] dealing with the mechanism of virus hæmagglutination, it was suggested that erythrocytes that had adsorbed the virus became hydrophobic, hence their tendency to cling to glass. This hydrophobic character of the virus – erythrocyte adsorption complex produces behaviour similar to that observed with oil droplets in an aqueous medium. That is, under the influence of surface tension the complex adheres to any surface with which it is in contact. It was further suggested that the aggregation of erythrocytes (hæmagglutination), as well as tendency to cling to glass (shield formation), could be explained in this fashion without the necessity of postulating virus 'bridges'[2] linking cell to cell and cell to glass.

Some further studies have been performed by treating the erythrocytes with ferric chloride and comparing the ability of these cells to cling to glass beads with the similar ability of cells treated with virus or virus plus a cationic surfactant. The addition of a cationic surfactant enhances the ability of virus to produce the tendency to cling to glass.

The treatment with ferric chloride involved diluting a solution of 0·5 *M* $FeCl_3.6H_2O$ containing 20·0 ml. of concentrated hydrochloric acid per litre with isotonic saline, just prior to use, to yield a concentration of 100 µgm./ml. Ferric chloride prepared in this manner yields no colour when treated with *o*-phenanthroline and gives an opalescent solution the opalescence of which gradually increases. Both facts suggest that a colloidal suspension, or a suspensoid, rather than a solution is produced.

With both ferric chloride and virus, the erythrocytes and the respective agglutinin were mixed to yield a final volume of 5·0 ml. Changes in optical density of the mixture at 540 mµ were followed and when no further changes were observed, or at least 15 min. had elapsed, 50·0 mgm. of glass beads with a mean diameter of 60µ were added. Before use these beads were washed in acid and repeatedly rinsed with distilled water. After addition of the beads, the tubes were inverted several times, the beads allowed to settle, and the optical density of the erythrocyte suspension was determined. This was repeated until the optical density remained constant. When erythrocyte suspensions without added agglutinin are treated in this fashion no change in optical density occurs when the glass beads are added; nor is any change observed when the erythrocyte suspension contains virus or virus plus 4 µgm./ml. of cationic surfactant. The results obtained when ferric chloride is added are presented in Fig. 1. In this case the erythrocytes cling to the beads and are carried down with them. In addition, a more drastic hæmagglutination is produced by the ferric chloride.

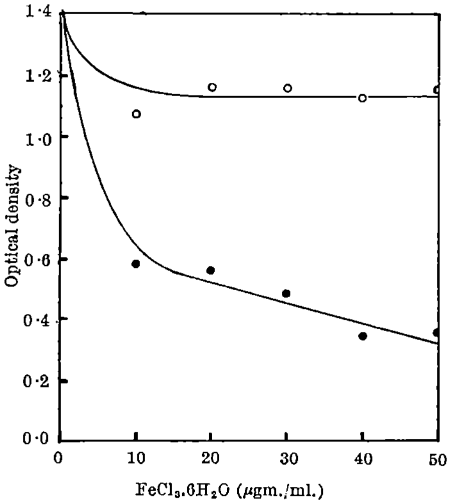

Fig. 1. Effect of concentration of ferric chloride upon the stability of a suspension of human erythrocytes in the presence or absence of glass beads. ○—○, Samples before adsorption with glass beads; ●—●, samples after adsorption with glass beads

These observations suggest that the forces responsible for virus hæmagglutination and the tendency to cling to glass are considerably weaker than those operating when ferric chloride is the agglutinin. In the latter case these forces would presumably be chemical bonding forces, or electrostatic interactions, or both. Thus, the observations are consistent with the postulate that surface tension, rather than virus 'bridges', underlies hæmagglutination and 'glass cling' of the virus – erythrocyte combination. Further support for this contention can be drawn from the study of electrostatic effects in virus hæmagglutination reported by Shingu[3].

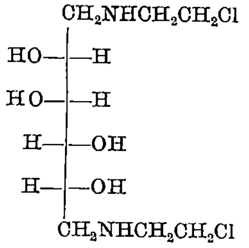
Tumour-inhibiting Action of 1 : 6-Dimethanesulphonyl-D-mannitol

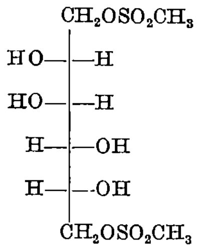
Extensive clinical experience with 'Myleran' (I, $n = 4$) in the treatment of chronic myeloid leukæmia[1] has shown that when over-dosage is avoided the drug is free from side-effects. On the other hand, other alkylating agents which are used clinically, namely, ethyleneimine derivatives and nitrogen mustards, usually cause some side-effects. This contrast may be attributable to a different mechanism of action for 'Myleran' and for the other alkylating agents. Evidence for this difference arises from comparison of the effects of 'Myleran' and a mustard (chlorambucil) on rat bone-marrow[2] and from a similar comparison where, when the drugs were used clinically in leukæmia, there was no enhanced excretion of uric acid after administration of 'Myleran' although nitrogen mustards and triethylenemelamine caused a significant rise in uric acid excretion[3]. 'Myleran' and its congeners (I), while they inhibit experimental tumours, cause a marked depression of bone-marrow function and cannot therefore be considered suitable for the treatment of solid tumours in man. In the 'Myleran' series there is evidence that variations in neutrophil-depressing and also in tumour-inhibitory activity may depend very much on the ratio between the solubility of the particular compound in water and in ether[4]. In the hope that a very large relative increase in water solubility might possibly minimize the bone-marrow depressing properties of the 'Myleran' series while leaving unaffected tumour-inhibitory activity together with the apparent clinical virtues attributable to the 'Myleran' type of action, we decided to modify the series by the insertion of hydroxy groups in the polymethylene chain. *Bis*-1:6-2′-chloroethylamino-1:6-dideoxy-D-mannitol (II) had been made because it was a type of nitrogen mustard which it was thought might inhibit glycolysis[5]. The fact that its tetrahydroxylated hexamethylene chain structure was consistent with tumour-inhibiting activity led us to choose 1 : 6-dimethanesulphonyl-D-mannitol (III) as the first member of our new series.

$CH_3SO_2O(CH_2)_nOSO_2CH_3$

(I)



(II)



(III)

1 : 6-Dimethanesulphonyl-D-mannitol was first prepared by the reaction of 1 : 2-5 : 6-dianhydro-3 : 4-*iso*propylidene-D-mannitol with methanesulphonic acid, in ether solution. As we expected, the two epoxide rings were split and addition of 2 mol. of methane sulphonic acid occurred, but the *iso*propylidene residue then evidently became highly labile and was lost by hydrolytic splitting in the presence of a trace of water taken up by the ether in the course of the experiment. The structure assigned was unequivocally shown to be correct by synthesis via benzylidenation of 1 : 6-dibenzoyl-D-mannitol, followed by debenzoylation, mesylation, acetolysis and methanolysis.

Under biological test, 1 : 6-dimethanesulphonyl-D-mannitol combines relatively low toxicity with powerful inhibition of the growth of the Walker rat carcinoma-256, and of a radiation-induced rat lymphatic leukæmia. Substantial inhibition has also been observed in the case of the exceptionally resistant 'August' rat carcinoma.

The investigation has been supported by grants to this Institute from the British Empire Cancer Campaign, the Jane Coffin Childs Memorial Fund for Medical Research, the Anna Fuller Fund and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

Note added in proof. Since submitting this communication, we have simplified the preparation of the drug by showing that successive treatment of D-mannitol with 2 mol. of methanesulphonyl chloride and 4 mol. of acetic anhydride in pyridine solution yields its tetracetyl derivative.

Forssman's Antigen in Ehrlich Mouse Carcinoma

THE question of whether a specific antigen exists in cancer tissue is receiving increasing attention. The view generally held is that carcinoma contains Forssman's[1] antigen.

Injection of rabbits with a cell suspension prepared from transplantable Ehrlich's mouse carcinoma gives rise to the formation of heterogenetic Forssman antibodies[2]. But two forms are known of Ehrlich's carcinoma ; (*a*) the solid tumour formed after subcutaneous inoculation, and (*b*) the ascites tumour seen after intraperitoneal injection.

Our investigation was made with the 'classic' Ehrlich transplantable tumour strain, which was placed at our disposal by Dr. Eva Melander, Institute of Genetics, University of Lund, Sweden.

By immunizing rabbits with cell suspensions of solid Ehrlich carcinoma we had no trouble in confirming Morgenroth's[2] statement ; but with the ascites carcinoma we could not reproduce his findings ; Forssman's antibodies could not be induced by injecting rabbits either with cells and liquid withdrawn from the peritoneal cavity of inoculated mice, or with cells or liquid separated by centrifuging.

The action of rabbits' sera was judged by their power to lake 5 per cent suspensions of sheeps' red blood corpuscles in the presence of complement. Examples of several tests, all with similar results, are shown in Table 1.

Table 1

Rabbit's serum	Hæmolytic titre	
	Before immunization	After immunization
Anti-Ehrlich carcinoma	1 : 100	1 : 4000
,,	1 : 10	1 : 2000
,,	1 : 10	1 : 1000
Anti-ascites carcinoma	1 : 50	1 : 100
,,	1 : 200	1 : 100
,,	1 : 50	1 : 50
Anti-ascites carcinoma cells	1 : 100	1 : 100
,,	1 : 50	1 : 20
,,	1 : 20	1 : 50
Anti-ascites carcinoma liquid	1 : 200	1 : 200
,,	1 : 100	1 : 50
,,	1 : 100	1 : 100

These results make one doubt whether Forssman's antigen is, in fact, a component of the Ehrlich mouse cancer cells at all. But this was confirmed by the following experiments.

Sera with known heterogenetic antibody content (anti-guinea pig kidney serum, and anti-sheep red-cell serum) were absorbed with either Ehrlich carcinoma or ascites carcinoma cells. Ehrlich carcinoma cells invariably suppressed the hæmolytic titres of these anti-Forssman sera. Ascites carcinoma cells, on the other hand, failed to do so.

Alcoholic extracts of both types of cell suspension were then prepared. Those of the Ehrlich carcinoma cells produced clear-cut ring reactions with the anti-Forssman sera when tested by Sachs and Guth's method[3]. Alcoholic extracts of the ascites carcinoma-cells invariably failed to react.

Ascites carcinoma, unlike Ehrlich carcinoma, appears to be free of heterophilic antigen. This seems surprising : (*a*) because the mouse is a Forssman's antigen-bearing animal, and (*b*) in view of the generally held opinion that cancers contain heterophilic antigen, even in Forssman-negative species.

Further consideration, however, shows that the histological structure of the two carcinomas differs in that Ehrlich carcinoma is rich in fibroblasts and capillaries; it has a rich stroma of mesodermic origin. Ascites carcinoma, on the other hand, consists of epithelial carcinoma cells with no other component except the peritoneal fluid suspending the cells. This certainly suggests that it is the stroma part of the solid tumour, and not the carcinoma cells as such that carries the heterophile antigen. This supposition finds support in a paper by Tanaka and Leduc[5], in which they state that Forssman's antigen in various normal organs of Forssman-positive species (guinea pig, mouse) is present mainly in the connective-tissue structures, and not in the parenchyma; it was located microscopically by the fluorescent antibody method. Although no similar data are as yet available concerning cancer tissues, this may prove to be correlated with our own findings. It should be possible to confirm this by the same technique[6].

Differences between the Early Metabolic Effects of Thyrotropic Hormone and Triiodothyronine

The physiological significance of triiodothyronine is still uncertain[1]. In previous reports[2] [3] rapid metabolic changes, possibly of thyroid origin, have been described in association with emotionally stressful life experiences in man. An investigation was therefore undertaken to see how soon metabolic changes could be demonstrated following triiodothyronine and thyrotropic hormone.

Observations on metabolic rate, pulse-rate, blood pressure and various urinary constituents were made at 2-hr. intervals for a period of 8 hr. in five healthy volunteer medical students following triiodothyronine (kindly supplied by Glaxo Laboratories) (0·5 or 1 mgm.) given intravenously as a single injection, and thyrotropic hormone ('Thytropar', kindly supplied by Armour and Co., Chicago) (0·44 U.S.P. units/kgm. body-weight) given intramuscularly. As a control observations were made following the intramuscular injection of saline. All studies were made in the fasting state using techniques previously described[4].

The rise in metabolic rate was greater with thyrotropic hormone than with triiodothyronine ($P < 0\cdot01$). The elevation with triiodothyronine was barely significant within this time ($P = 0\cdot07$) (Table 1).

Table 1. Mean Effect of Thyrotropic Hormone and Triiodothyronine on Metabolic Rate (cal./sq.m./hr.)

Treatment	Time (hr.) 1	3	5	7
Saline	39·5	39·9	41·3	42·3
Triiodothyronine	38·9	40·7	42·1	43·7
Thyrotropic hormone	38·0	40·8	44·2	46·2

The associated elevation of pulse-rate with thyrotropic hormone was significantly greater than with triiodothyronine ($P < 0\cdot01$) which did not differ from the control; elevation of pulse pressure was also observed following thyrotropic hormone but not following triiodothyronine. Significant elevation of serum protein-bound iodine has been previously noted within 4 hr. following thyrotropic hormone in similar dosage[5].

However, triiodothyronine produced a greater increase in inorganic phosphate excretion ($P < 0\cdot025$), similar to that previously described[4], indicating a different metabolic effect from that of thyrotropic hormone (Table 2).

Table 2. Mean Effect of Thyrotropic Hormone and Triiodothyronine on Inorganic Phosphate Excretion (mgm./min.)

Treatment	Time (hr.) 0–2	2–4	4–6	6–8
Saline	0·39	0·47	0·53	0·53
Triiodothyronine	0·46	0·46	0·80	1·04
Thyrotropic hormone	0·37	0·49	0·55	0·47

Transient increases in sodium and potassium excretion within the first 4 hr. were noted following thyrotropic hormone ($P < 0\cdot05$) but not following triiodothyronine.

The specificity of these changes following thyrotropic hormone was confirmed when it was given in similar dosage to a series of five hypothyroid subjects on maintenance dosage of desiccated thyroid (Table 3).

Table 3. Mean Effect of Thyrotropic Hormone on Metabolic Rate in Five Hypothyroid Subjects on Thyroid (cal./sq.m./hr.)

Treatment	Time (hr.) 1	3	5	7
Saline	34·4	33·6	35·1	36·3
Thyrotropic hormone	34·1	34·2	36·0	36·9

The effect of thyrotropic hormone on the metabolic rate was significantly less than in the normal subjects ($P < 0\cdot001$); the rise in pulse-rate was also less ($P = 0\cdot07$); no increase in sodium and potassium excretion occurred. The mean increase in metabolic rate was proportionately greater in the normal subjects (21·6 per cent) than in the hypothyroids (8·3 per cent).

These findings suggest that the early effect of thyrotropic hormone differs from that of triiodothyronine but is still of thyroid origin. They support previous suggestive evidence obtained from observations made during emotionally stressful life experiences in man[2] [3] of a rapidly active thyroid hormone distinct from triiodothyronine.

In this connexion it is of interest that the calorigenic effect of desiccated thyroid is greater than that indicated by its 'thyroxine iodine content'[6]. Similar findings have been reported with thyroglobulin[7,8]. Such discrepancies appear to be too great to be accounted for by the minute amounts of triiodothyronine recovered from the thyroid[9].

In a recent chromatographic study no increase in triiodothyronine could be demonstrated in the plasma following thyrotropic hormone in euthyroid subjects[10].

The observations reported here indicate that the early metabolic effect of the thyroid secretion under stimulation by thyrotropic hormone is not accounted for by triiodothyronine. They provide evidence of a rapidly active thyroid hormone distinct from triiodothyronine as previously suggested[5].

Further investigations are in progress and more detailed findings will be published elsewhere.

We are indebted to Dr. A. T. James, Division of Mathematical Statistics, Commonwealth Scientific and Industrial Research Organization, for the statistical analyses.

An Anticlumping Factor for Mitochondria in the Supernatant Fraction of Rat-Liver Homogenates

In a rat-liver homogenate that has not been strongly diluted the mitochondria remain substantially unclumped for several hours even at room temperature; but if it is diluted more than about five-fold with a medium containing electrolyte, serious clumping may occur in a few minutes. If it is diluted with the supernatant from another homogenate which has been only slightly diluted, clumping is almost completely inhibited. This shows that a natural anticlumping factor is present in the supernatant. The factor is thermolabile, non-dialysable and precipitable from supernatant by half-saturated ammonium sulphate. Its activity is lost gradually at 0° C. but is retained indefinitely at − 15° C. The lability suggests that it is not identical with heparin, which is known to prevent mitochondrial clumping. This is confirmed by the fact that our factor does not, like heparin, produce nuclear haloes[1] by combining with histone and liberating deoxyribonucleic acid. On the other hand, all its properties known so far correspond with those of the ribonuclease inhibitor discovered by Roth[2,3], which is also not identical with heparin although the latter inhibits ribonuclease. We therefore tested crystalline pancreatic ribonuclease for clumping activity and found it very potent in absence but not in presence of supernatant, as expected. Thus there is good reason for accepting as a working hypothesis that our anticlumping factor and Roth's ribonuclease inhibitor are identical, though this can be established with certainty only by isolation of the two substances. Our factor, like Roth's, varies greatly in concentration in apparently similar preparations. One supernatant had perceptible anticlumping activity at a dilution of 1/180, suggesting that even crude concentrates of the factor will be useful protectors in any experiments where mitochondria need to be kept in good condition.

The quantitative assessment of mitochondrial clumping is not easy. We tried various indices, for example the ratio of total clumps (including single mitochondria) to total mitochondria, or the number of mitochondria in the largest clump in a field. Finally, we made a scale consisting of nine numbered photographs of mitochondria clumped by incubation with ribonuclease for varying times, and chosen so that the general impression of clumping in adjacent photographs was just perceptibly different (Fig. 1). Other photographs were then assigned 'clumping numbers' from 0 to 8 by matching against the standards. This principle, whereby the scale unit is defined in terms of the unit of subjective discrimination, is the basis of the well-known Munsell colour scale[4] and was used by Bourdillon and his co-workers[5] in assessing rickets in rats.

A rough test of accuracy was performed by asking eleven judges, separately, to place the nine standard photographs in order. Comparing their rankings with the expected order, it was found that no judge displaced the rank of any photograph by more than ± 2 units and that such displacements occurred in only three of the 99 cases. The greatest mean displacement of a photograph, averaging over the eleven judges, was 0·36 unit. The distribution of the 99 displacements was [see over]:

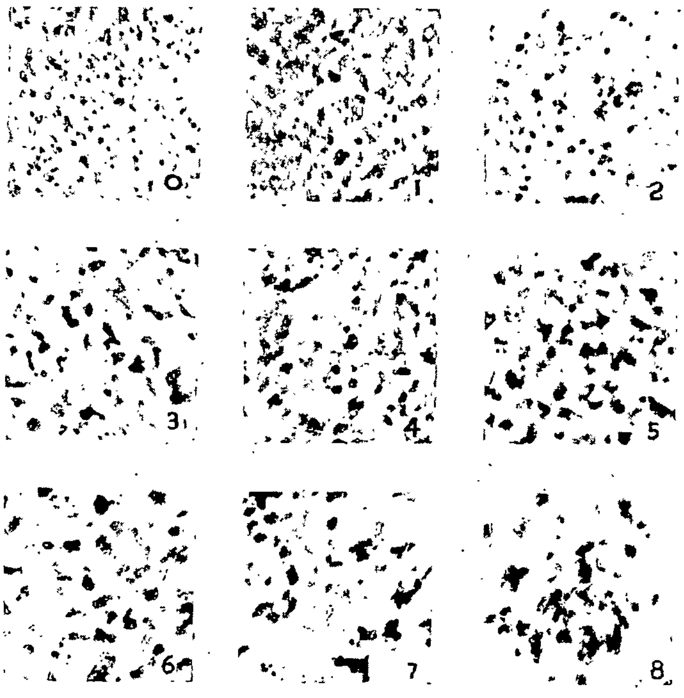

Fig. 1. Photographic scale for assessment of mitochondrial 'clumping number'

Displacement units	−2	−1	0	+1	+2
Frequency	1	13	72	11	2

The distribution is leptokurtic. The root-mean-square displacement is 0·6 unit. The coefficient of concordance[6] is 0·95 and is highly significant. Thus there is a marked measure of agreement between the rankings of the eleven judges, and their average judgment agrees with the expected order. The use of clumping numbers to demonstrate the clumping action of ribonuclease and the anti-clumping action of liver supernatant is shown in Fig. 2. The amount of supernatant used in this experiment gave 98 per cent inhibition of the breakdown of added ribonucleic acid by the same amount of ribonuclease.

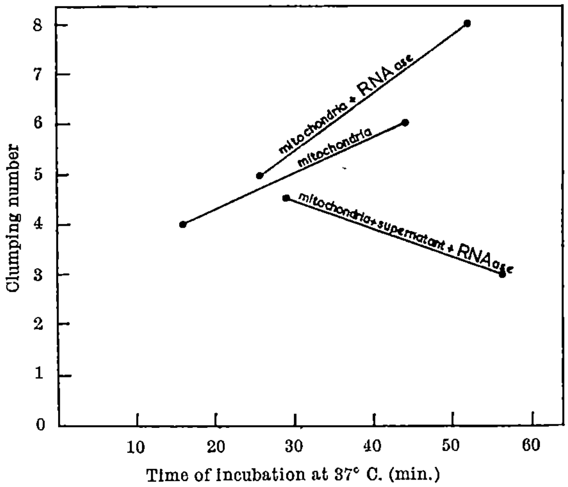

Fig. 2. Enhancement of clumping of mitochondria by added ribonuclease, and protection by supernatant. The mitochondria were washed with and suspended in 0·3 M sucrose, 0·1 M sodium chloride, 0·01 M potassium phosphate pH 7·8, with the addition of 0·005 γ/ml. crystalline pancreatic ribonuclease (top line) or 0·005 γ/ml. ribonuclease + liver supernatant at a dilution of 1/180 (bottom line)

If mitochondrial clumping is commonly due to the action of endogenous ribonuclease, the fact that it is promoted by electrolytes in general, which are known to activate ribonuclease[7], is readily explained. In addition, however, the divalent cations Ca^{2+} and Mg^{2+} seem to have a clumping action out of proportion to their effects on ribonuclease. This action seems to be partly reversible by chelating agents such as ethylenediamine tetraacetic acid, and by dialysed half-saturated ammonium sulphate fraction of supernatant. We therefore tested the latter for calcium chelating power colorimetrically with ammonium purpurate. Although the technique was imperfect it sufficed to show that the calcium-binding capacity of the anti-clumping fraction of supernatant per atom of nitrogen is about five times greater than that of whole supernatant. Thus the anti-clumping fraction may protect mitochondria by reversing the action of calcium as well as by preventing the action of ribonuclease. The two phenomena can be explained simultaneously by supposing that mitochondria are kept apart by negatively charged phosphate groups of ribonucleic acid, and that these charges can be abolished either reversibly by combination with calcium ions or irreversibly by hydrolysis of the ribonucleic acid. Although there is not much ribonucleic acid in mitochondria there is probably enough to satisfy this hypothesis, provided that it is mainly at the surface.

We wish to thank Miss S. Gibbons for assistance and Mr. D. R. Westgarth for statistical advice.

Hyperglycæmia induced in Rabbits by 5-Hydroxytryptophan

Administration of large doses of 5-hydroxytryptophan (60–100 mgm./kgm.) to rabbits produces marked central effects, for example, mydriasis, hyperpnœa, tachycardia, tremor and ataxia[1,2]. These effects seemed to be similar to those observed after giving lysergic acid diethylamide[1]. As lysergic acid diethylamide very markedly raises the blood-sugar level in the rabbit by a central action[3,4], 5-hydroxytryptophan should also produce hyperglycæmia if its central effect is similar to that of lysergic acid diethylamide.

Blood-sugar measurements were made using the modified method of Shaffer and Hartmann[5] in the blood of the ear artery of rabbits. It was found that 5-hydroxytryptophan given intravenously in small doses (5–20 mgm./kgm.) definitely raised the blood-sugar level. Fig. 1 shows the blood-sugar rise after 10 mgm./kgm.; Fig. 2 shows the dose–response curve, plotted on a logarithmic scale.

5-Hydroxytryptophan had to be given in doses at least 200 times higher than those of lysergic acid diethylamide to produce a comparable hyperglycæmic effect. 5-Hydroxytryptophan was also much weaker than lysergic acid diethylamide in producing a rise in body temperature (see ref. 6). Unlike lysergic acid diethylamide, however, 5-hydroxytryptophan elicited a hyperglycæmic effect when smaller doses were given than those required to produce an increase in body temperature[6].

During aprobarbital anæsthesia it was not possible to elicit hyperglycæmia with 5-hydroxytryptophan (20 mgm./kgm.). This suggests a central effect as

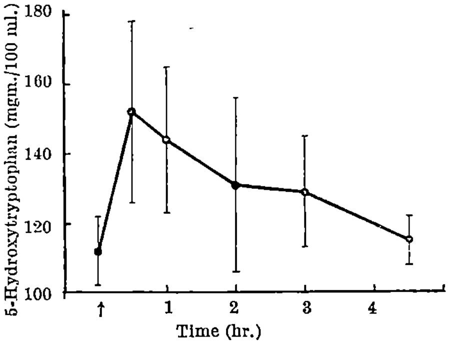

Fig. 1. Hyperglycæmic action of 10 mgm./kgm. 5-hydroxytryptophan (given intravenously at †). The vertical lines indicate the standard deviation of results obtained from nine animals ($P < 0·001$ for the highest value)

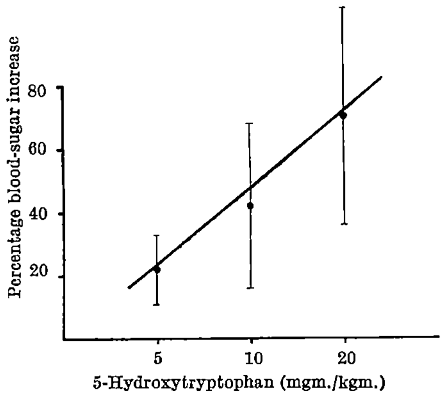

Fig. 2. Dose response curve for the hyperglycæmic action of 5-hydroxytryptophan administered intravenously. The mean response to 5 and 10 mgm./kgm. was established in nine animals, to 20 mgm./kgm. in six. The vertical lines indicate the standard deviation of results. Statistical calculation showed that the regression line did not depart significantly from linearity

in the case of lysergic acid diethylamide, whereas the blood sugar increase due to the peripheral action of adrenaline does occur under aprobarbital.

The hyperglycæmic effect of 5-hydroxytryptophan, which is the precursor of 5-hydroxytryptamine, may be of interest since 5-hydroxytryptamine can, under certain conditions (depancreatized dogs), produce a rise in blood sugar[7] and since the pancreas exhibits a high degree of 5-hydroxytryptophan-decarboxylase and mono-amino oxidase activity[8].

Lathyrism in Mice

IT is known that rats fed on a diet containing 50 per cent sweet-pea (*Lathyrus odoratus*) seed develop severe bony deformities, and that if young animals are used a proportion die of rupture of the aorta[1,2]; β-amino-propionitrile has a similar effect[3]. Few workers had previously attempted to produce lathyrism in mice, and their reports suggested that mice were refractory. Preliminary experiments, however, showed that aortic lesions in mice could be obtained, and while this work was in progress Dasler and Milliser[4] reported the production of aortic lesions in male weanling mice by feeding them on *L. odoratus* seeds; injection of high doses of β-amino-propionitrile gave, in addition, bony lesions. Experiments were continued with the aim either of confirming Dasler and Milliser's work and producing lathyrism in a cheap and easily handled animal or, if the mouse were resistant, of using this difference in response between two such closely related species as the rat and the mouse for investigation of the pathogenesis of lathyrism.

Porton mice were used, and either fed on a diet containing sweet-pea seed or injected with β-amino-propionitrile. The diet consisted of 40–50 per cent *Lathyrus odoratus* seed, finely ground, mixed with ground rat-cake (diet 86) and reconstituted into cubes with water; β-amino-propionitrile was given as the hydrochloride by subcutaneous injection of a 1 : 10 solution in distilled water; dosage was approximately 0·1 ml./10 gm. body-weight.

In all 200 mice were treated. In 152 treatment started either *in utero* or in the suckling period. Thirty mice from various litters were eaten or unfit for histology; in addition, four entire litters of mothers treated during pregnancy were destroyed by the mothers, and are not included. Forty-five mice which either died or were killed before the age of two weeks were examined: all had histological lesions of the aorta, and approximately half had aortic rupture. In 77 mice, treatment was continued either *per os* or by injection for a varying period after weaning: in 53 aortic lesions were present. Thirty-three mice started treatment when between 2 and 5 weeks of age (injected or weaned on to the sweet-pea diet): seventeen had histological lesions. Fifteen mice started treatment when more than 8 months old: none had significant lesions.

The aortic lesions can conveniently be divided into two main groups. In all infant mice treated *in utero* or in the first few days of life by feeding or injecting the mother there is a characteristic change in the elastica, which is thinned and often interrupted. A proportion of the young die—some of aortic rupture. These experiments show clearly that the toxic principle passes the placenta and is also excreted in the milk.

In the older mice, thinning of the elastica is not observed. Instead, there is rupture of elastic laminæ ranging in severity from rupture of individual laminæ to total rupture of the aorta. Rupture of individual laminæ is occasionally seen in untreated old mice, but not in young animals.

As in rats, aortic lesions are produced only in young animals, though the dosage required to produce aortic lesions in mice is higher. The period of maximum susceptibility was found to extend from the last week of intra-uterine life to the fifth week of post-natal life. Within these limits the younger the animal the easier it is to produce lesions. If treatment is given to the mother during the first two weeks of pregnancy and then stopped, the young are born healthy, though histologically the elastica is abnormal, particularly the outer layers, which are thinned. Treatment started after 5 weeks of age has no effect.

A difference in the susceptibility of the sexes has not been reported in rats, whereas in mice sex markedly affects results. When treatment is given *in utero* or in the first few days of life, both sexes are affected. However, if started at 2 weeks of age or later, aortic damage occurs predominantly in the male. It is noteworthy that Dasler and Milliser[4] used only male mice, and it seems probable that had they used mice of both sexes they would have produced fewer aortic lesions. Again, in contrast with the rat, mice do not develop bony lesions with the dosage I have used.

Menzies and Mills[5] suggested that in rats the primary lesion is in the ground substance, and that proliferation of fibroblasts precedes elastic damage. The histology in mice shows clearly that, in infant mice at least, there is an alteration in the elastica before any increase in ground substance can be recognized. Also, in sections from adult mice, rupture of elastic fibres is frequently seen in the absence of any fibroblastic proliferation. Lastly, no alteration in the muscle cells is apparent in any of the sections. This leaves the elastica as the element primarily affected.

The fact that the period of susceptibility coincides with the period of maximum growth suggests that the condition is not one of degeneration of the elastica but rather of malformation.

My thanks are due to Dr. G. W. Crosbie of the Biochemistry Department, University of Glasgow, for preparing the β-amino-propionitrile.

Day-length and Hæmatin Compounds in Plants

IT has been shown that day-length regulates the chlorophyll content of many plants[1-3] and that this is a true photoperiodic phenomenon[4]. In leguminous plants, day-length controls both the chlorophyll content and the number and efficiency of the root nodules[5,6]. It seems that, in this case, both the synthesis of hæmoglobin in the nodules and the synthesis of chlorophyll in the leaves are depressed by short day-length. Moreover, there are indications that in some plants (tobacco, for example), the ratio between the quantity of chlorophyll and the quantity of total hæmatin in the leaves remains constant over a wide range of concentrations (Davenport, H., personal communication).

I therefore thought it of interest to investigate whether day-length influences hæmatin-content as it does chlorophyll-content. I studied simultaneously the chlorophyll and total hæmatin during long-day (16 hr.) and short-day (8 hr.) in four species: soya bean (*Soja hispida*), lupin (*Lupinus albus*), wild strawberry (*Fragaria vesca*), and hemp (*Cannabis sativa*). Total hæmatin was measured by the method of Hill and Scarisbrick[7]. Chlorophyll was measured with the Beckman spectrophotometer in 80 per cent acetone using the formula of Mackinney[8].

As shown in Fig 1, in mature leaves there was generally a constant molar ratio of about 60 molecules of chlorophyll to 1 molecule of hæmatin.

In the leguminous plants, soya bean and lupin, the ratio remains constant on changing from long to short days and vice versa. Short-day treatment reduces the hæmatin- and chlorophyll-content of the leaves simultaneously and to the same extent, while long-day treatment increases both. In the leaves, there is about 20–30 per cent less hæmatin during short-day than during long-day (Table 1). The decrease is not only evident in the leaves, but also in the roots. With the lupin, some nodules during short-day had a hæmatin-content 50 per cent lower than in the long-day control. These facts support the idea that, in the leguminous plants, the lack of nodule formation and efficiency in short-day is due to a general hæmatin deficiency, itself related to a marked depression of chlorophyll content in short-day. The occurrence of such a relation between hæmatin and chlorophyll is particularly striking when one considers the photoperiodic control of flowering.

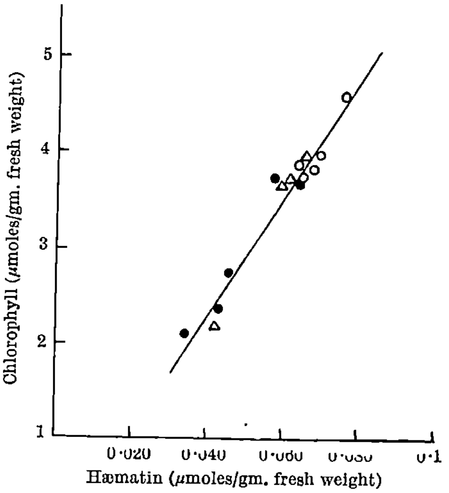

Fig. 1. Relation between hæmatin- and chlorophyll-content in mature leaves. (For lupin and soya bean, the different chlorophyll contents were obtained in different day-length conditions; for hemp, the figures are for long-day only.) ●, lupin; ○, hemp; △, soya bean

In wild strawberry, which does not flower when grown in short-day, we find a much lower hæmatin-content in the mature leaves in short-day than in long-day (in agreement with the decrease in chlorophyll content). But the opposite occurs in hemp, a plant in which flowering is immediately induced by short-day. A typical experiment is shown in Fig. 2. In long-day, hemp shows the normal molar ratio chlorophyll/hæmatin of about 60. If one transfers it at the stage of four expanded leaves from long- to short-day, the chlorophyll content immediately decreases[2]. In this particular case, however, instead of decreasing, the hæmatin content increases (the molar ratio chlorophyll/hæmatin drops to 30–40). In short-day, there is about 30 per cent more hæmatin than in long-day. The transformation is very rapid. It needs only five short days to show a significant effect in the fourth leaf. It is entirely reversible. After five short days, the transfer back to long-day leads to an increase of chlorophyll content and a decrease of hæmatin. The molar ratio chlorophyll to hæmatin returns to its normal value of 60. At the same time, induction of flowering stops.

Table 1. EFFECT OF DAY-LENGTH ON HÆMATIN CONTENT IN LUPIN AND SOYA BEAN
Hæmatin in µmoles/gm. fresh weight

Organs analysed	Day-length	Lupin			Soya bean	
		Series No.			Series No.	
		1	2	3	1	2
Adult leaves (*a*)	Long	0·058	0·046	0·065	0·060	0·066
	Short	0·043	0·035	0·037	0·046	0·043
Roots (*b*)	Long	0·017	0·014	0·011	0·016	—
	Short	0·012	0·010	0·007	0·008	—
Nodules	Long	0·270	0·144	—	—	—
	Short	0·124	0·083	—	—	—

(*a*) The following leaves have been analysed: in lupin, leaf No. 12 (series 1 and 2) and leaf No. 14 (series 3); in soya bean, leaf No. 1 (series 1) and leaf No. 2 (series 2).

(*b*) In lupin, the principal roots have been analysed; in soya bean the total roots including the secondary roots.

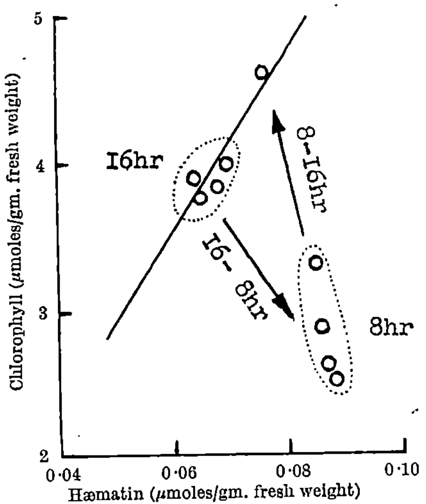

Fig. 2. Effect of transfer from long to short days and vice versa on chlorophyll/hæmatin ratio in hemp. (The arrows indicate directions of transfer; see text)

Further details of these experiments will be published elsewhere. I am greatly indebted to Dr. R. Hill for valuable help in the method of measuring hæmatin in leaves, to Prof. F. G. Young for providing facilities in the Department of Biochemistry, Cambridge, to Mr. J. Gilmour, director of the Botanical Garden, Cambridge, for growing the plants, and to the I.R.S.I.A. (Belgium) for financial support.

Occurrence of Coumarin Analogues in Lemon Juice

THERE has been little or no investigation of coumarin compounds in lemon juice although their presence in lemon oil has been well established[1–4].

It was of interest to determine whether coumarin analogues were indeed present in lemon juice. Petroleum ether extracts of California lemon juice concentrates were examined by the chromatostrip technique of Miller and Kirchner[5]. This revealed a group of eight fluorescent spots suggestive of the coumarin array demonstrated by Stanley and Vannier[4,6]. Extracts were then subjected to downward chromatostrip development[6] and separation of four of the compounds was achieved in amounts adequate for qualitative ultra-violet spectral measurements. Comparison of R_F values with known coumarin compounds and ultra-violet absorption spectra tentatively identified these four compounds as 5-geranoxypsoralen (bergamottin), 5-geranoxy-7-methoxycoumarin, 8-geranoxypsoralen and 5,7-dimethoxycoumarin (limettin) (Table 1).

Table 1

Compound	$R_F \times 100$*	Ultra-violet absorption maxima (mµ)
5-Geranoxypsoralen	68	251, 259, 269, 310
5-Geranoxy-7-methoxycoumarin	64	246, 256, 325
8-Geranoxypsoralen	40	244, 250, 265, 300
5,7-Dimethoxycoumarin	25	246, 256, 325
Oxypeucedanin hydrate	5	250, 259, 268, 310
Byakangelicin	0	241, 249, 270, 313

* On silicic acid chromatostrips (refs. 5, 6). Irrigation solvent: 25 per cent ethyl acetate in *n*-hexane (v/v).

The possibility remained that the coumarin compounds detected in the juice could conceivably be present because of inclusion of lemon oil in the concentrate. This could come about during the mechanical reaming of the fruit resulting from the rupture of the oil sacs releasing small amounts of oil into the juice[7].

In order to determine whether these coumarin compounds were present in oil-free lemon juice the following experiment was performed.

Thirty-six lemons were thoroughly scrubbed and washed in a hot detergent solution and rinsed with water. The lemons were then allowed to soak in hot water for about 30 min.

The epicarp (flavedo) was carefully stripped from each fruit by means of a stainless steel knife, and the fruit rinsed in cool water. The mesocarp (albedo) and segment membranes of the fruit were then removed and the lemons quartered. Finally the central vascular bundle and all the seeds were removed.

The sectioned juice sacs were homogenized in a blendor for 15 min., and the homogenate filtered to remove any remaining membrane material. 250 gm. of this material were extracted with three 100-ml. portions of low-boiling petroleum ether, the extracts combined, dried over anhydrous sodium sulphate, filtered and the solvent removed under reduced pressure on a steam-bath. A pale yellow oil resulted. A small amount of the oil (about 0·01 ml.) was applied to a silicic acid chromatostrip[6] and irrigated with a solution of 25 per cent ethyl acetate in *n*-hexane. Examination of the strip under ultra-violet light (2540 A.) revealed eight distinct spots or zones.

Several downward chromatostrips[5] were run, the individual zones scraped from the strip, each eluted with 95 per cent ethanol and the eluates filtered. The ultra-violet spectrum of each eluate was then taken.

Comparison of R_F values with known coumarin compounds and ultra-violet absorption spectra tentatively identified five of these compounds as 5-geranoxypsoralen (bergamottin), 8-geranoxypsoralen, 5,7-dimethoxycoumarin (limettin), oxypeucedanin hydrate and byakangelicin (Table 1).

To date, insufficient amounts of these compounds have been isolated from the juice for more precise analytical examination; but this work is in progress.

Further Aspects of Humus Decomposition

Recent experiments have shown that the characteristic flush of decomposition that follows the wetting of a dry soil can be partly prevented by the addition of 0·5 gm. of activated charcoal (per 30 gm. soil) and almost completely prevented by 1·5 gm. or more (Fig. 1). When the soils were then oven-dried and re-wetted without further treatment a similar result was obtained. When a slowly decomposing moist soil was treated with ether vapour under vacuum and the excess vapour then removed, a similar flush of decomposition resulted which was also repeated with successive treatments. Here, however, the flush of decomposition was not inhibited by charcoal.

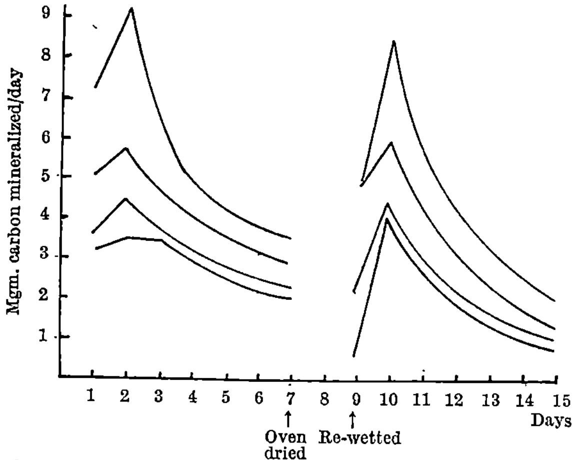

Fig. 1. Curves, from top to bottom: no carbon; 0·5 gm. carbon; 1·0 gm. carbon; 1·5 gm. carbon

These results afford an insight into the factors involved in humus decomposition and the partial sterilization of soils. Soil drying increases the amount of organic material later going into solution and when this is adsorbed by the charcoal the flush of decomposition is inhibited. Ether vapour has, however, been found here to have no effect on the amount of organic material that will dissolve. Nevertheless, the flush of decomposition still occurs and this may be ascribed to the high microbial activity associated with the youthful phase of the newly developing population and the presence of dead microbial cells which can serve as readily available substrate[1].

Since heat causes diffusion of amino-acids from within the cells[2], it is possible that the compounds adsorbed by the charcoal are amino-acids or similar microbially derived compounds and that these, serving as available substrate, are responsible for the flush of decomposition following the wetting of an oven-dry soil. Ether, on the other hand, reduces cell permeability[3] and was found here to be ineffective in increasing the amount of organic material going into solution. Charcoal, therefore, has no effect after ether treatment in inhibiting the flush of decomposition which must depend on the utilization of relatively intact dead cells as substrate. Clearly, the marked decomposition that follows partial sterilization is not necessarily dependent on increased solubility of substrate. The main factor involved appears to be microbial death, whether accompanied by lysis of the cell contents or not, the remains then serving as available substrate when normal conditions are restored. The newly developing population will also be more active at first than later on.

The results of the charcoal experiment conform with what has been said. It will be noted that the magnitude of the second flush of decomposition is related to the magnitude of the first. The larger this is the bigger the microbial population will be and the greater the amount of substrate available, after killing, for the succeeding population. Such a sequence of decompositions can, however, only be maintained if substrate additional to that supplied by the micro-organisms is available, since much of the microbially derived substrate is lost as carbon dioxide during its utilization by the newly developing population. It has been reported[4] that when decomposable material is added to a soil a highly active microbial population develops with consequently enhanced humus decomposition while the supply of energy material lasts. Microbially derived substrate could serve a similar function, the succeeding population building up to an equilibrium-level depending not only on the amount of microbially derived substrate available but also on the kind and amount of humus present. This would explain why the sequence of decompositions are of approximately equal magnitude and are also dependent on the carbon content of the soil.

Chlorine Deficiency in Soils

In the past five years chlorine has been shown to be an essential micronutrient for a number of vegetable and crop plants[1,2]. More recently, the need for chlorine was demonstrated in the annual pasture plant, subterranean clover (*Trifolium subterraneum*, L.)[3]. The solution culture medium used in these experiments was prepared by adding highly purified inorganic salts to twice-distilled water. In addition, the plants were grown in glasshouses fitted with filters to purify the incoming air.

The economic importance of chlorine as a plant nutrient will depend on whether or not plant growth in the field is limited by chlorine deficiency. Although a great deal of information has been accumulated regarding saline soils, there is little known of the occurrence of soils very low in chlorine. As a first step in investigating this problem, I collected soil samples from various locations in California. These were selected with regard to distance from the sea, high altitude, heavy rainfall or with permeable, well-drained soil profiles. It was thought that these conditions were likely to produce soils low in chlorine. On analysis of saturation extracts by electrometric titration, the two soils lowest in chlorine were found to contain only three to five micro-equivalents per 100 gm. These soils, a Holland sandy loam and a Cometa coarse, sandy loam, were found in the foothills of the Sierra-Nevada Range at points about 65 miles apart, and 100 miles from the ocean. Both sites were carrying a poor growth of annual pasture plants.

Subterranean clover (var. Mt. Barker) was planted in 2·4-kgm. pots containing these soils, and then

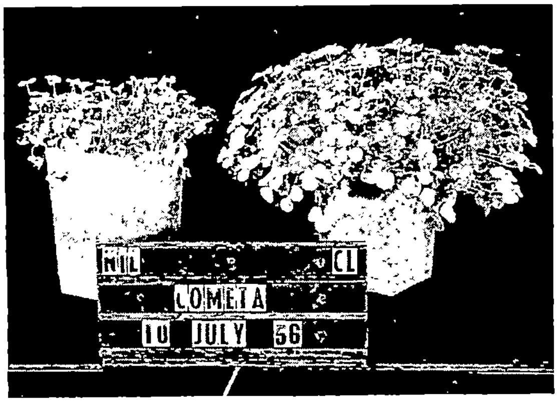

Fig. 1

grown in a glasshouse at the University of California, Berkeley. To half the pots, ample chlorine for plant growth was added; in the others the only chlorine present was that in the soil. All the pots were supplied with a complete nutrient solution, lacking only in chlorine. The plants were watered with twice-distilled water. At intervals of 3–4 weeks the plants were mown back to simulate the defoliating effects of grazing.

After three and a half months, acute symptoms of chlorine deficiency were present on the 'minus-chlorine' plants on both soils, and the top yields of these plants were reduced. The type of culture technique and the yield effects on one soil type are shown in Fig. 1. Under the conditions of the experiment these soils did not contain sufficient chlorine to grow the clover plants even to the flowering stage.

A similar exploratory soil survey has now been carried out in Western Australia. Here, despite the areas of saline soils and salt lakes in the inland agricultural areas, three soils containing only 3–5 micro-equivalents of chlorine per 100 gm. were found. Two of these soils were potted in 5-kgm. containers in the glasshouse at Perth. They were then planted with subterranean clover. Again, as in the Californian trial, acute chlorine deficiency symptoms developed before the plants reached the flowering stage. In this experiment no air filters were used on the glasshouse, which stands only 150 yards from a salt-water estuary and five miles from the ocean.

The amount of chlorine present in the soils described is equivalent to about 4 lb. per acre—6 in., or the depth of the pots used. Much of the chlorine in soils is derived from the rainfall. Hence, it is of interest to note[4] that five rural areas in Victoria receive little more than this amount in the annual rainfall.

This work is continuing and will be reported in more detail elsewhere. However, it is apparent that a number of soils contain insufficient chlorine for plant growth when the plants are repeatedly defoliated under glasshouse conditions.

Use of Loosely Linked Genes to estimate Chromatid Interference by Tetrad Analysis

STRICKLAND[1] has applied to tetrad data for *Aspergillus nidulans* the method I have suggested[2] for estimating the magnitude of chromatid interference between cross-overs when loosely linked genes are used. The principle underlying this method is as follows: Consider three linked loci X, Y and Z spaced along a chromosome in that order. By means of tetrad analysis one can distinguish a number of tetrad genotypes. Certain of these, called (*a*), (*b*) and (*c*), respectively, are most simply interpreted as resulting from the following cross-overs at meiosis: (*a*) One cross-over between X and Y and another between Y and Z involving the same chromatids, that is, a two-strand double cross-over. (*b*) One cross-over between X and Y and another between Y and Z, with a three-strand relationship. (*c*) One cross-over between X and Y and another between Y and Z involving the other two chromatids, that is, a four-strand double cross-over. With closely linked genes, the frequencies of (*a*), (*b*) and (*c*) provide accurate information about the frequencies of two-, three- and four-strand relationships between cross-overs. If the genes are loosely linked, these tetrad genotypes can also arise as a consequence of a three-strand double cross-over between X and Y (or Y and Z) and a third cross-over between Y and Z (or X and Y), but the strand-relationships with the third cross-over are two- or four-strand for genotype (*b*) and three-strand for genotypes (*a*) and (*c*). In other words, the occurrence of these triple cross-over tetrads will hinder the detection of chromatid interference by tending to obscure differences from the 1 : 2 : 1 proportion of genotypes (*a*), (*b*) and (*c*). This is the ratio expected with no chromatid interference. The frequency of these inconvenient triple cross-over tetrads can be estimated from the observed frequency of another tetrad genotype (*d*), which results from a four-strand double cross-over between X and Y (or Y and Z) and a third cross-over between Y and Z (or X and Y). In this way, allowance can be made for the effects of triple cross-overs.

If the frequencies of tetrads of genotypes (*a*), (*b*) and (*c*) do not differ significantly from a proportion of 1 : 2 : 1, there are two alternative explanations, namely, either (1) successive cross-overs occur at random (or nearly so) as regards the pair of strands involved, or (2) there is chromatid interference, but its occurrence has been obscured owing to triple cross-overs. In the latter event, analysis of a larger number of tetrads should reveal a significant deviation from 1 : 2 : 1, since only a minority of the tetrads are likely to arise from triple crossing-over. Thus, from his analysis of 264 tetrads from "cross 2", Strickland[1] obtained frequencies of genotypes (*a*), (*b*) and (*c*) of 34, 66 and 24, respectively. These frequencies do not differ significantly from a proportion of 1 : 2 : 1 ($\chi^2 = 2{\cdot}13$ $n = 2$, $P = 0{\cdot}5$–$0{\cdot}3$). There were 15 tetrads of genotype (*d*) and consequently the contribution to the (*a*), (*b*) and (*c*) genotypes due to triple cross-overs can be estimated (as a first approximation) to be $\frac{66}{24} \times 15 = 41{\cdot}25$, or 33·3 per cent. Thus it is probable that about two-thirds of the 124 tetrads of genotypes (*a*), (*b*) and (*c*) have resulted from double cross-overs and consequently have provided valid information about the strand-relationships between cross-overs. Analysis of a larger sample of tetrads will therefore be expected to provide a significant deviation from 1 : 2 : 1 if there is chromatid interference. However, from Strickland's published data it is not justifiable to conclude that there is such interference, since hypothesis (1) above has not been ruled out. In other words, the 'correcting' of chromatid interference data to allow for triple cross-overs can be used for estimating the magnitude of such interference but not for detecting its occurrence in the first place.

Cytochromes of *Rhizobium*

LEGHÆMOGLOBIN, the red pigment associated with the bacteroid form of *Rhizobium* in effective legume root nodules, appears to be closely linked with the nitrogen fixation process[1], but its connexion with *Rhizobium* respiration is disputed[2,3]. We are endeavouring to clarify the latter problem by a comparative study of respiratory pigments in several free-living *Rhizobium* strains and the related root nodules.

While observing with a microspectroscope the reduction of leghæmoglobin in fresh homogenates of effective soybean or clover nodules made anaerobic by endogenous respiration, we saw also a sharp absorption band appearing near 551 mμ. This was later identified as the α-absorption band of reduced bacteroid cytochrome *c*, and it therefore appeared that biological reduction of the two pigments could be closely related. A smaller amount of *b*-type cytochrome, with α-absorption band at 562 mμ, was also seen in the washed bacteroids isolated from these homogenates, but no cytochrome *a* could be detected even when dense bacteroid suspensions in 50 per cent (v/v) glycerol were examined in the spectroscope at liquid air temperature (cf. Hartree[4]). Typical cytochrome *a*, *b* and *c* absorption bands as described by Smith[5] were readily observed in the same *Rhizobia* grown on an agar medium, showing that, in the transition from free-living to bacteroid form, *Rhizobium* loses its cytochrome *a*.

Many micro-organisms suffer an adaptive loss of cytochrome *a* when grown anaerobically[6], and as the nodule interior is assumed to be at a very low oxygen tension[2] we then made a quantitative comparison of cytochrome components in effective soybean nodule bacteria and the same *Rhizobium* strain grown in pure culture at high and low oxygen tensions. Cytochrome concentrations were measured in a Bellingham and Stanley reversion microspectroscope following the general procedure described by Hartree[4]. The comparison prism of this instrument was remounted so that the bacterial spectrum and the comparison spectrum (of reduced mammalian cytochrome *c* contained in a wedge-trough) were viewed simultaneously. By turning the reversion screw, the α-absorption band of the standard cytochrome *c* was matched in turn against each cytochrome band of the bacterial spectrum. An arbitrary assumption was made that the α-absorption bands of all components had the same specific extinction coefficient as cytochrome *c*.

These measurements (Table 1, *A*) showed an increase of cytochromes *b* and *c* in effective nodule bacteria (bacteroids) and cultured *Rhizobium* grown at low oxygen tension, and confirmed the complete loss of cytochrome *a* from bacteroids. Cytochrome *a* had decreased in amount, but not disappeared from the cultured organisms grown at an oxygen pressure of 0·02 atm. We were unable to grow *Rhizobium* in liquid culture at oxygen tensions lower than this and so could not decide whether the complete disappearance of cytochrome *a* from bacteroids is solely due to a very low oxygen tension inside the effective nodule. Subsequent measurements (Table 1,*B*) on *Rhizobium* isolated from ineffective soybean nodules (which were devoid of leghæmoglobin and caused no detectable nitrogen fixation), made this explanation seem unlikely, as these bacteria still contained a small amount of cytochrome *a*.

Table 1. CYTOCHROME CONCENTRATIONS IN *Rhizobium* FROM ARTIFICIAL CULTURE AND NODULES

Rhizobium strain (5)	Origin	Cytochrome component	α-Band (mμ)	Conc. in pellet (m*M*)	Nitrogen content (mgm./ml. of pellet)
A					
505 Wisconsin	Culture Oxygen pressure =0·2 atm.	*c*	551	0·096	38
		b	562	0·036	
		a	602	0·023	
505 ,,	Culture Oxygen pressure =0·02 atm.	*c*	551·5	0·160	37
		b	563	0·044	
		a	602·5	0·012	
505 ,,	Effective nodule	*c*	551·5	0·270	29
		b	562·5	0·059	
		a	—	0	
B					
507 ,,	Culture Oxygen pressure =0·2 atm.	*c*	551·5	0·050	28
		b	562·5	0·038	
		a	601·5	0·021	
507 ,,	Ineffective nodule	*c*	551·5	0·108	27
		b	562·5	0·033	
		a	602	0·006	

The bacteria were isolated from vigorously aerated log-phase liquid cultures and from 6–7-week-old nodules of 'Lincoln' strain soybean grown in the glasshouse. After checking for purity the washed *Rhizobium* suspensions were reduced with dithionite, and the pellets obtained after high-speed centrifuging (30,000*g*) were placed in demountable spectrophotometer cuvettes of 1, 2 or 3 mm. light path. Cytochrome contents, determined as described in the text, are expressed as millimolar concentrations in the packed pellets. Total nitrogen values were determined by the Kjeldahl method.

Work is at present in progress to determine what function cytochrome *a* has in the terminal oxidase system of *Rhizobium*[7], and whether its unique disappearance from bacteroids is accompanied by the appearance of another oxidase which might react specifically with leghæmoglobin.

Reproductive Disturbances of Romney Ewe Lambs grazed on Red Clover (*Trifolium pratense*) Pastures

On March 10, 1958, 111 Romney ewe lambs (group *A*) which had grazed continuously since weaning (December 12, 1957) on pastures dominant in red clover were joined with an additional 92 Romney ewe lambs (group *B*) for studies of their breeding season. This latter group had grazed, since weaning (December 11, 1957), on perennial rye-grass–white clover pastures. Vasectomized, ochred rams were run with these lambs from March 17, 1958, all being grazed together on perennial rye-grass–white clover pastures. All lambs were weighed on March 19, group *A* and group *B* having the same average live weight (71 lb.). On the same day, that is, within two days of joining with teasers, 29 lambs from group *A* but none from group *B* were found to have been marked. This sudden onset of œstrus from one group of lambs was unexpected in view of the previous results[1] on the breeding season of Romney ewe lambs. Owing to the relatively early age at first œstrus shown by these lambs, laparotomy was performed within five days of observed œstrus to determine whether ovulation had occurred. Both the left and right ovaries of eight lambs were examined without finding any evidence of the existence of corpora lutea. Graafian follicles of varying sizes, however, were seen on most ovaries.

Red clover[2], like Australian subterranean clover[3], has been reported to contain substances with œstrogenic effects. In order to investigate whether the observed œstrus without ovulation in the lambs described earlier could have resulted from the œstrogenic activity of the red clover dominant pastures, random samples of this pasture were collected on March 25. These samples, consisting almost entirely of red clover, were freeze-dried, ground in a hammer mill and fed to 21-day-old, ovariectomized white mice in an attempt to detect the presence of substances with œstrogenic effects by the mouse uterine weight technique[4]. The control diet consisted of 50 per cent (by weight) barley meal and 50 per cent butter milk powder. The 'clover' diet was made up from 75 per cent (by weight) control diet and 25 per cent 'clover' pasture. Results from two feeding periods of 10 and 11 days respectively were combined and are presented in Table 1.

Table 1. THE EFFECTS OF FEEDING 'CLOVER' DIET TO MICE (SEVEN MICE PER GROUP)

Treatments	Control	'Clover'
Initial body-wt. (gm.)	8·76	8·64
Final body-wt. (gm.)	15·10	10·07
No. of vaginal openings	1*	7
Mean and S.D. of uterine wt. (mgm.)	5·36±0·99	10·57±2·67

* Suspected to be an artefact.

These results indicate that the 'red clover' pastures contained substances which have potent œstrogenic effects. It is also probable that ingestion of 'red clover' pastures over a period of time as occurred in the present case has induced œstrus without ovulation in the lambs. It is of interest to note that Australian workers[5-7] have repeatedly pointed out that lowered fertility of breeding ewes grazing subterranean clovers was not attributable to the failure of œstrus as detected by ochred rams. If the present findings are also applicable to breeding ewes, then under certain conditions, 'œstrus without ovulation' may represent an additional complication in studies of female infertility in sheep.

Grateful acknowledgment is due to Dr. D. S. Flux, Prof. A. L. Rae and Mr. B. Thatcher for assistance and discussion.

Molybdenum Content of Equine Liver Tissue

The discovery that molybdenum is a component of the enzyme xanthine oxidase[1] has directed interest to the presence of this element in animal tissue, particularly liver. I have found that adult horse liver tissue contains highly variable levels of molybdenum.

125 specimens of adult horse liver were obtained from a Cambridge slaughter-house during a period of eight months. The liver samples were dried at 100° C. and the dried material analysed for molybdenum by the thiocyanate–stannous chloride method of Dick and Bingley[2]. The range of molybdenum content of the tissues is shown in Fig. 1.

While 109 of the 125 livers were within the range 3–19 p.p.m., five livers had molybdenum-levels of 42·0, 47·6, 54·8, 76·4 and 84·6 p.p.m. of tissue dry-matter. The total ash contents of these latter five samples were within the normal range.

Comparing these figures with the data given by Underwood[3], it has been found that molybdenum accumulates in the liver to a greater extent in the horse than in cattle or sheep. The reason for the accumulation of this element is not known, but it is

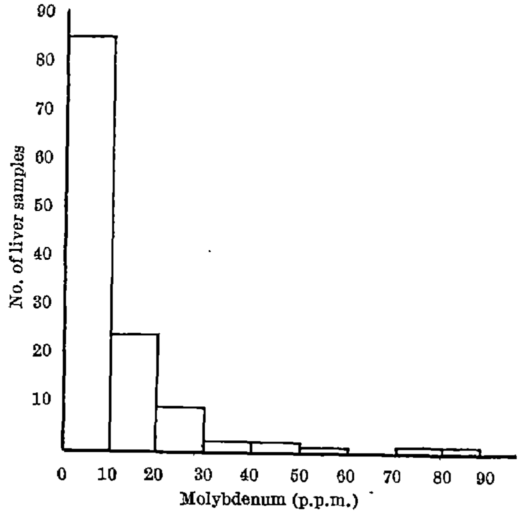

Fig. 1. Range of molybdenum contents of 125 samples of equine liver

possibly associated with the advanced age of individual animals. The rise in molybdenum may also reflect changes in the enzyme activity of the liver with age.

Serological Test for Determination of Parentage in Cattle

The antigenic individuality of red cells of cattle was noted in 1910 [1], and studies conducted since 1940 by many workers have made it possible to identify more than fifty blood factors. The number of blood-group combinations is very large, and in practice it is difficult to find two individuals with the same combination. Identification of red cell antigens in cattle and knowledge of the mode of inheritance of these characters have been found to have a practical application among others in the exclusion of paternity and the control of pedigree. A condition for the efficacy of these tests is the possession by the laboratory of a large number of immune sera (reagents).

In 1950 Löns[2], basing his argument on antigenic individuality of human red cells, proposed the method of determining paternity by the use of polyvalent immune serum. He assumed that the polyvalent serum absorbed by the red cells of the father and the mother would react with the red cells of all other persons with the exception of the red cells of a child of the couple the red cells of which were used for the absorption. This method did not yield the expected results and control tests proved it to be useless.

Prof. F. Milgrom suggested to us that an analogous method might be successful for the determination of parentage in cattle.

In order to obtain polyvalent sera, rabbits were injected with red cells of 20 different cattle. The resulting sera hæmolysed in high titre the red cells of all cows, and the absorption of the serum with red cells of one animal removed the antibodies for the red cells used for absorption and left antibodies for all other samples of blood. Out of nine immune sera obtained, two (Nos. 919 and 345) could be successfully used in further tests; their absorption was relatively easy. The absorption conditions were specific for each serum. The best absorption formula was determined by a procedure similar to that used in determining the method of absorption of rabbit anti-*M* or anti-*N* antisera (of the *MNSs* system in humans). Sera Nos. 919 and 345 were absorbed in dilutions of 1 : 25 and 1 : 45 respectively. The volume of red cells used for absorption ranged from 1/1 to 1·5/1, depending on the antigen power of the red cells. The absorption time for serum 919 was 2·5 hr. and for serum 345, 4 hr. Further details concerning the technique employed will be described elsewhere by one of us (J. R.).

For absorption, a mixture of red cells of the mother and the father was used. After absorption, a hæmolysis test was made with the red cells of the offspring. As a control, tests were performed with red cells used for absorption and with red cells of about twenty other cattle. These red cells came from: (1) the offspring of only one of the couple the red cells of which were used for the absorption—these cattle are denoted in Table 1 as 'related'; and (2) cattle regarded as 'unrelated'. These were unrelated or showed a lesser degree of relationship than the cows in group 1. As a complement, guinea pig serum diluted 1 : 10 was used. This serum was previously controlled to see that it did not contain antibodies for cattle red cells.

Table 1. Results of Tests with the use of Two Polyvalent Sera

Material tested	Results obtained with serum No. 919: Number tested	919: Parentage excluded	345: Number tested	345: Parentage excluded	919+345 together: Number tested	919+345 together: Parentage excluded
Offspring	41 *1·000**	0 *0·000*	41 *1·000*	0 *0·000*	41 *1·000*	0 *0·000*
Related individuals	142 *1·000*	80 *0·563*	146 *1·000*	81 *0·554*	140 *1·000*	86 *0·614*
Unrelated individuals	663 *1·000*	528 *0·796*	662 *1·000*	527 *0·796*	650 *1·000*	579 *0·891*

* Figures in italics denote the percentage of the number tested.

After absorption the sera never reacted with the red cells employed for absorption nor did they react with the red cells of cows that were the offspring of the couple the red cells of which were employed for absorption. In contrast to this, these sera reacted with the majority of control red cells both with the samples from the 'related' and 'unrelated' heads of cattle. 35 families with 41 offspring were studied. Control tests were made with 140 'related' and 650 'unrelated' individuals. Table 1 gives the results of our tests.

From these results it appears that the use of two polyvalent sera makes possible the exclusion of about 89 cows out of 100 that were not the offspring of the couple the red cells of which were used for absorption. When the tested individual is an offspring of only one of the heads the red cells of which were used for absorption, exclusion of parentage is still possible in 61 per cent of cases. The first of the figures given, 89 per cent, is almost the same as giving positive indication of the proper pair of parents in the case when it was not possible to exclude the parentage.

It seems that the method described will be of practical use in checking doubtful parentage since the method is incomparably more simple and more within the scope of an ordinary laboratory than the method employed hitherto in which many reagents difficult to obtain are used. The efficiency of the method is quite good; this method could be increased if a third polyvalent serum were used.

Variations in the Insecticide Tolerance of Insects

Recent communications[1,2] on the variance of the dosage-mortality response of strains of housefly and mosquito susceptible and resistant to insecticide serve to emphasize that, although there is considerable information on the inheritance of resistance to insecticide in some insects, especially houseflies[3], *Drosophila*[4] and now mosquitoes[5], there has as yet been no direct estimate of how much of the unselected tolerance is genetically determined, how much is due to environmental effects. Beard[6], who first directed attention to the possibilities, considered the non-genetic variation might so predominate as to overwhelm the genetic components.

One would not wish to dispute the contention[1] that insect populations comprised of a single resistance-susceptibility genotype are likely to be less variable in their tolerances than are populations containing all possible resistance-susceptibility genotypes. But that fact is scarcely relevant to what Hewlett originally suggested[7], namely, that a portion of the tolerance variance is susceptible to manipulation without any change in gene frequency. That this interpretation was, at least in part, intended is shown by the example selected[8], the decrease in variance of the tolerance found with a DDT-resistant strain of housefly when increasing amounts of the insecticidally inert synergist DMC were added to the applied DDT. One point which strongly supports Hewlett's hypothesis, but has not been commented upon, is the very obvious increase in variance with the smallest amount of DMC compared with that found with DDT alone[8].

It is usual to assume that the genes for resistance are extremely rare in Nature, or, as stated by Wilson-Jones and Davidson[1], so infrequent that an average sample of wild insects is unlikely to contain resistant genes. This assumption has been made repeatedly in attempts to explain the often rather slow emergence of resistance in the field, but, as was recently pointed out[9], it is unlikely that this assumption of rarity is correct. Indeed, the only quantitative work as yet available on the frequency of resistant genes in wild populations showed that there may be as many as 12 per cent of dieldrin-resistant heterozygotes in the *Anopheles gambiae* populations of areas as yet untouched by dieldrin[10]. Finally, laboratory populations originate as samples from wild populations, most but not all attempts in the laboratory to induce insecticide resistance are successful, and sometimes resistance to a number of insecticides can be developed sequentially[11].

Fluorescent Mast-Cell Reaction in Precancerous Skin of the Lizard *Lacerta agilis*

The mast-cell reaction of the mouse skin, painted with tar or carcinogenic hydrocarbons, has been known for a long time[1]. According to several authors, these cells show a golden-brown fluorescence when examined under the microscope in ultra-violet light[2], though other investigations give some evidence to the contrary[3].

Recently, it has been established that the mast cells of the mouse and the rat contain not only histamine but also 5-hydroxytryptamine[4]. This substance can be converted into a fluorescent β-carboline derivative by the action of formaldehyde, and in the mast cells of the precancerous mouse skin it reaches a concentration which is normally only achieved by the cells of the enterochromaffin system[5].

In the mastocytosis of the mouse skin after painting with 9,10-dimethyl-1,2-benzanthracene in acetone it could be demonstrated to direct assay and by paper chromatographic examination that the fluorescent substance of the mastocytes is the 5-hydroxytryptamine derivative β-carboline[2].

Continuing these investigations, we examined a cutaneous carcinoma of a lower vertebrate, namely, the squamous-cell carcinoma of the lizard *Lacerta agilis*. This tumour seemed pre-eminently suitable for this purpose, because a distinct precancerous phase occurs in its development[6,7]. At first we had seven tumour-bearing animals, but by extending the material we finally had 104 specimens at our disposal.

From these specimens the precancerous portions of the skin were excised. The examination of the mast cells was carried out with frozen sections (cut in a horizontal as well as in a vertical direction), free-hand sections and tissue spreads prepared from dermal scrapings. The skin material, fixed in 10 per cent formalin or otherwise, was examined under the microscope in ultra-violet light. Then the material was stained either with acetylated sudan black for phospholipids[8] or with toluidine blue for mast cells.

Just as in the mouse, the mast cells of the precancerous skin of the lizard gave a golden-brown fluorescence in ultra-violet light, but only after treatment with formalin. The fact that a non-fluorescent precursor substance can be extracted from the mast cells by prolonged treatment of the skin tissue with acetone suggests that the fluorescence is a consequence of the action of formaldehyde on the above-mentioned substance. Acetone treatment apparently did not affect the ability of the mast cell granules to stain with either acetylated sudan black or with toluidine blue.

To establish the chemical identity of the fluorescing substance we prepared an extract of the precancerous lizard skin. For this purpose the dermal scrapings of the skins were homogenized in acetone, after which the extract was concentrated *in vacuo*. After the fats had been removed with petroleum ether the extract was treated with formaldehyde and could then be examined in ultra-violet light. The extract treated with formaldehyde exhibits the same golden-brown fluorescence as was found with the extract of mouse skin prepared in the same way[2]. A further extraction of the skin fragments with fat solvents failed to yield additional fluorescent material.

Like the mast cells of the precancerous mouse skin, the mast cells of the precancerous skin of the lizard probably contain a relatively large quantity of histamine and 5-hydroxytryptamine.

The source of 5-hydroxytryptamine is unknown; it may be either the inside or the outside of the precancerous epidermis. Possibly this substance plays an important part in the development of the squamous-cell carcinoma of the skin.

Undergraduate Academic Record of Fellows of the Royal Society

The communication by Gross and Hudson in *Nature* of September 20, p. 787, shows an interesting difference between academic records of Fellows of the Royal Society who were respectively at Cambridge and at Oxford. Of those at Cambridge only about 77–78·5 per cent achieved a first, and in fact only about 55 per cent achieved a first in both parts of a tripos. The Fellows of the Royal Society who were at Oxford, on the other hand, graduated with first-class honours in about 97 per cent of cases.

The authors suggest that these interesting results are open to at least two interpretations: (1) that the Oxford examination is a more valid index of potential research ability; and (2) that the standards of the Oxford examinations are relatively lower than those of Cambridge. There is surely a very important third possible interpretation, namely, extra-curricular activities are far more interesting at Cambridge than at Oxford, and that in the widest sense the Cambridge education is therefore better.

The authors, strangely, make no comment on the fact that it seems to be three times as common for a Cambridge graduate to become a Fellow of the Royal Society, neither do they comment on the obvious fallacy of the whole investigation, namely, the opportunities for research offered to a young man at the beginning of his career. If these are, for example, only offered to those with a first-class degree, it is obvious that selection for the fellowship of the Royal Society in later years will be almost restricted to those who had first-class degrees. The method will fail to show whether there is a number of potentially good investigators among those with second-class degrees who have never been given the opportunities for a career in research.

Robert Platt

Department of Medicine,
The Royal Infirmary,
Manchester 13.

We certainly agree with Prof. Platt that the difference between the Oxford and Cambridge results is open to the third possible interpretation that he suggests, and we would welcome from him any suggestion as to how we could measure the "more interesting" nature of the "extra-curricular activities" at Cambridge.

We find nothing strange in "the fact that it seems to be three times as common for a Cambridge graduate to become a Fellow of the Royal Society" since there are almost three times as many science graduates from Cambridge as there are from Oxford.

During the period 1920–39, approximately 4,700 natural scientists, 1,400 mathematicians and 1,800 engineers graduated from Cambridge, while only 2,600 natural scientists (including engineers) and 400 mathematicians graduated from Oxford.

If we understand Prof. Platt's last paragraph correctly, we consider it to be true but irrelevant to our study and to the general problem under consideration. Obviously, as he points out, if only students with first-class degrees are given opportunities for research, the Fellows of the Royal Society will be drawn largely from this group. Our point is that, whatever selection procedures were used in the past, a considerable minority of the scientists elected to the Royal Society did not receive first-class degrees. From this we conclude that it may be unwise to use class of degree as the primary criterion for the award of research grants.

C. Gross
L. Hudson

Psychological Laboratory,
Cambridge.

Cancer and Smoking

In a letter published in *Nature* of August 30, p. 596, Sir Ronald Fisher quoted figures confirming previous observations that smoking habits are more similar in identical than in fraternal pairs of twins even when the identical pairs are reared apart. The result can be interpreted as showing that, like almost every trait, mental or physical, previously tested by the twin method, smoking habits are, to a greater or lesser degree, dependent upon genetical constitution. It is, however, difficult to appreciate the relevance of this demonstration to the problem as to whether or not cigarette smoking causes lung cancer.

The association between epithelioma and the occupation of sweeping chimneys has been well known in the past. Not improbably it could have been proved that identical twins were more often both chimney sweeps than would have been expected by chance. Such a finding would not have influenced the case for assuming a strong causal connexion between soot irritation and epithelioma.

Nevertheless, there are perhaps hitherto unexplored ways in which twin data might be usefully employed in the study of the effects of tobacco on the lungs. Pairs of identical twins, whose smoking habits were discordant, could be followed up with special reference to possible development of lung disorders in one or both members.

London, W.C.1.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Monday, October 27

Institute of Actuaries (in Staple Inn Hall, High Holborn, London, W.C.1), at 5 p.m.—Mr. F. M. Redlington: Presidential Address.

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Mr. A. T. Grove: "Geomorphology of the Tibesti Region".

Institution of Electrical Engineers, Radio and Telecommunication Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. J. Swaffield and Mr. D. L. Richards: "Rating of Speech Links and Performance of Telephone Networks"; Mr. D. L. Richards and Dr. J. Swaffield: "Assessment of Speech Communication Links".

Royal Aeronautical Society (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 6 p.m.—Mr. D. J. Farrar: "The Bloodhound".

Tuesday, October 28

University of London (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Prof. J. Z. Young, F.R.S.: "Octopuses, Squids and Cuttlefishes".*

University of London (at Queen Mary College, Mile End Road, London, E.1), at 1.30 p.m.—Prof. G. E. Newell: "The History of a Beach".*

Institution of Mechanical Engineers (at 1 Birdcage Walk, Westminster, London, S.W.1), at 2 p.m.—Symposium on "Aluminium Pressure Vessels".

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Electronic Control of Machine Tools" opened by Mr. D. T. N. Williamson.

University of London (in the main Chemistry Theatre, Royal College of Science, Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Dr. H. Zemanek (Vienna): "Some Automata of the 18th Century".*

Society of Instrument Technology (at Manson House, Portland Place, London, W.1), at 6 p.m.—Dr. L. Essen: "Basic Measurements of Time and Frequency".

Plastics Institute, London and District Section (at the Wellcome Building, 183–193 Euston Road, London, N.W.1), at 6.30 p.m.—Mr. B. S. Dyer: "Vinyl Chloride Polymers—Their Design and Application".

Institution of Electronics (in the Assembly Hall of the University of London Institute of Education, Malet Street, London, W.C.1), at 7 p.m.—Dr. F. E. Flood: "Electronic Telephone Exchanges".

Royal Institute of Chemistry, London Section (at the Medway College of Technology, Maidstone Road, Chatham, Kent), at 7.30 p.m.—Prof. R. S. Nyholm, F.R.S.: "Recent Advances in Structural Inorganic Chemistry".

Wednesday, October 29

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. P. Fourman: "Magnesium Metabolism".*

Society of Chemical Industry, Food Group—Nutritional Panel (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Meeting on "Nutritional Problems in Polar Regions". Lieutenant Commander A. B. Erskine, R.N.: "Sledging Problems"; Major J. M. Adam, R.A.M.C.: "Use of M.R.C. Sledging Rations".

British Institution of Radio Engineers (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Dr. M. Prutton: "Ferro-Electrics and Computer Storage".

Society of Chemical Industry, London Section (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 6.30 p.m.—Programme of Scientific Films pertaining to Atomic Energy. "The Dounreay Sphere"; "Engineering at Calder Hall"; "Criticality".

British Association of Chemists (at the Royal Society of Medicine (West Hall), 1 Wimpole Street, London, W.1), at 7 p.m.—Mr. J. Wilson: "Grant-Aided Research Associations" (Hinchley Memorial Address).

Thursday, October 30

University College (in the Anatomy Theatre, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. L. B. Keeble: "The Role of Town Planning in Modern Society".*

Friday, October 31

Institution of Mechanical Engineers (in conjunction with the Applied Mechanics Group, at 1 Birdcage Walk, Westminster, London, S.W.1), at 6 p.m.—Mr. W. Johnson: "Estimation of Upper Bound Loads for Extrusion and Coining Operations".

North East Coast Institution of Engineers and Shipbuilders (in the Lecture Theatre of the Literary and Philosophical Society, Newcastle-upon-Tyne), at 6.15 p.m.—Sir John Cockcroft, O.M., F.R.S.: "Nuclear Power for the Propulsion of Commercial Shipping" (Andrew Laing Lecture).

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. D. Bernal, F.R.S.: "The Structure of Liquids".

Saturday, November 1

Mammal Society of the British Isles (in the Meeting Room of the Zoological Society of London, Regent's Park, London, N.W.1), at 10.30 a.m.—Symposium on "Mammals in British History and Prehistory".*

London County Council (at the Horniman Museum, London Road, Forest Hill, London, S.E.23), at 3.30 p.m.—Mr. C. P. Mountford: "The Aborigines of the Central Australian Deserts".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Advisory Officer (with a degree in science or agriculture, preferably with honours, and experience in investigations or research concerning poultry husbandry) in Poultry Husbandry—The Secretary, North of Scotland College of Agriculture, 41½ Union Street, Aberdeen (October 31).

Experimental Physicists (preferably with an honours degree in physics or equivalent and a sound experimental physics background) in the Research and Development Department, Central Electricity Generating Board for work on nuclear reactors, particularly on experimental reactor physics during the commissioning of civil nuclear power stations—The Personnel Officer, Central Electricity Generating Board, 24–30 Holborn, London, E.C.1, marking envelope "Confidential—Ref. N/308" (November 3).

Reader (with high academic and research qualifications) in the Department of Physics; and a Lecturer or Assistant, Grade B (preferably with teaching and research experience), in the Department of Physics—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (November 7).

Assistant Experimental Officer (with a pass degree or equivalent) in the Department of Physiology and Plant Culture, for duties concerned with day-to-day routine work on plant studies in controlled environments—The Secretary, John Innes Horticultural Institution, Bayfordbury, Hertford (November 8).

Assistant in the Department of Botany—The Secretary, The University, Edinburgh (November 8).

Assistant Librarian (honours graduate) in the Science Section of the College Library—The Registrar, University College of North Wales, Bangor, North Wales (November 8).

Lecturer or Assistant Lecturer in Sociology (with special reference to Social Anthropology)—The Secretary, The University, Exeter (November 8).

Technical Officer (Mass Spectrometer) (with a degree or diploma in chemistry or physics or equivalent qualifications) in the School of Chemistry, New South Wales University of Technology, Kensington, N.S.W., Australia, to maintain and operate a MS2 Metropolitan Vickers Mass Spectrometer—The Agent-General for New South Wales, 56 Strand, London, W.C.2 (Australia, November 12).

Chairs in Botany, Chemistry, Mathematics, Physics, and Zoology in the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (November 15).

Lecturer in the Department of Social Anthropology, School of African Studies, University of Cape Town—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa, November 15).

Scientific Officer (with a first- or second-class honours degree in biochemistry or a closely related subject, and preferably some research experience) in the Department of Biochemistry, to engage in the study of problems of plant biochemistry, in particular the influence of mineral nutrition on the enzyme content of leaves—The Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (November 17).

Lecturer in Civil Engineering at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 29).

Senior Lecturer or Lecturer in Mechanical Engineering at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 29).

Lecturer (with a degree in mechanical engineering of a recognized Commonwealth university, preferably at honours standard, or an equivalent qualification, and preferably experience of modern drawing office practice) in Mechanical Engineering at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand, November 30).

Senior Lecturer and Lecturer in Geology at the University of Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, November 30).

Assistant, Grade B (graduate well qualified in mathematics) in Mathematics—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex.

Assistant Lecturer, Grade B (with a good honours degree and preferably some teaching experience) in Chemistry at Brighton Technical College, to teach general chemistry up to G.C.E. advanced level standard and to assist with the teaching of inorganic chemistry at degree level—The Director of Education, County Borough of Brighton Education Committee, 54 Old Steine, Brighton, Sussex.

Biochemist, Senior or Basic grade (with a B.Sc. degree with honours in chemistry or biochemistry or an equivalent qualification)—The Group Secretary, Royal Hospital, Wolverhampton.

Biometrician (graduate in mathematics with an interest in biology) in the Section of Statistics, for duties which involve consultation on research on the design and analyses of experiments—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berks, quoting Ref. 58/17.

Chemist (with a Ph.D. or good honours degree, and preferably experience in, or knowledge of, electro, surface or theoretical organic chemistry), to join a team investigating the fundamentals of corrosion—The Director, Arthur D. Little Research Institute, Inveresk Gate, Musselburgh, Midlothian, Scotland.

Experimental Officers (at least 26 years of age with the H.N.C., or equivalent, in applied physics), to carry out experimental work in support of a programme of development of high speed trigatrons and associated circuitry—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berkshire, quoting Ref. A.1968/1/34.

Lecturer in the Department of Mining and Fuels, for duties mainly concerned with the teaching of fluid mechanics and mine ventilation—The Registrar, The University, Nottingham.

Lecturer (with a degree in horticulture) in Horticulture at Massey Agricultural College (University of New Zealand), Palmerston North, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1.

Lecturer (with an honours degree in chemistry and postgraduate experience of academic or industrial research) in Physical and Inorganic Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Mullard Research Fellow (with a good degree in electrical engineering or physics of a British university or equivalent qualification) in the Department of Electrical Engineering, for work on microwaves—The Secretary, University College, Gower Street, London, W.C.1.

Publications Editor/Librarian (with an honours degree in arts or science, some editorial experience, an interest in agricultural research, and preferably previous library experience or training and a knowledge of one or more foreign languages)—The Secretary, Grassland Research Institute, Hurley, near Maidenhead, Berks.

Research Assistant in Chemistry, to work in the field of complex metal reactions—The Secretary, Department of Chemistry, University College, Gower Street, London, W.C.1.

Seed Mycologist (with a degree in botany and preferably some postgraduate training); and a Research Assistant (with a degree in botany), for work on cereal germination—The Secretary, National Institute of Agricultural Botany, Huntington Road, Cambridge.

Senior Lecturer in Inorganic Chemistry, to plan and supervise the teaching of inorganic chemistry up to honours degree standard—The Principal, Royal Technical College, Salford.

Senior Research Assistant (Ph.D. standard and preferably some experience of electronics) in Physics, for a programme of work on the magnetic properties of thin films—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey.

Technician in the Nuclear Engineering Laboratory, for research work in electronics and nucleonics—The Registrar (NT), Queen Mary College (University of London), Mile End Road, London, E.1.

Technician or Junior Technician, for biochemical work in the Hospital Metabolic Unit—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2.

Zoologist or Physiologist (with a degree), to assist in the British Empire Cancer Campaign research on the biology of cancer including tissue culture—The Administrative Office, Mount Vernon Hospital, Northwood, Middx.

MARINE ECOLOGY

by

HILARY B. MOORE

Professor of Marine Ecology and Asst. Director of Marine Laboratory, University of Miami.

In this work the author views his subject as the meeting place of many sciences and surveys the various disciplines that bear on the study of marine ecology. He employs physical and chemical oceanography to describe and explain the physical and chemical aspects of the environment. He discusses the use of physiology and animal behaviour in understanding the reactions of organisms to particular conditions.

TECHNOLOGY OF COLOMBIUM (NIOBIUM)

Edited by

B. W. GONSER & E. W. SHERWOOD

Colombium is a metal that has much to offer for the designer of structures destined to operate at high temperatures. Accordingly a symposium on colombium (niobium) was planned by the Electrothermics and Metallurgy Division of the Electrochemical Society, and this volume contains most of the papers read at it.

SCIENTIFIC AND INDUSTRIAL RESEARCH: THE STATE AND INDUSTRY

IN an earlier article (*Nature*, October 25, p. 1111), a general indication was given of the activities of the Department of Scientific and Industrial Research, and the relations of the Department with other government departments interested in aspects of scientific and industrial research were discussed. We now come to consider the relations of the Department's work with the research associations and industry, in the light of the comments made in the fifth report for the session 1957–58 of the Select Committee on Estimates*.

The Estimates Committee confines its criticism to two aspects: information services and financial recoveries from industry. While in general it is satisfied that the proportion of effort devoted to information services, at present about a quarter of the work of all the establishments, is a reasonable one and likely to achieve good results, it found two weaknesses. Stressing the importance of an individual approach under modern conditions, it believes it is a mistake not to approach individual firms which might be expected to be interested in particular results, and recommends that officers of establishments should be encouraged to write to, and to visit personally, individual firms or associations representing a particular industry likely to be interested in any results achieved by the establishments. Secondly, it regards some of the publications of the establishments as too general or nebulous in character· Unless a publication is of obvious direct and specific interest, it has little chance of attracting attention, and it may even tend to discourage the reading of the Department's publications generally. The sound suggestion is made that, before embarking on any publication of its own, the Department should be perfectly clear as to who it wishes to interest by the information to be given, and design the publication accordingly.

Beyond this estimate that the Department as a whole is spending something of the order of £1–£1·25 million on information services, the report gives no indication of the actual expenditure on the Headquarters Information Division, and some of the activities of the latter which have been freely criticized by information officers and librarians escape notice. Nor is there any recognition in this report of the importance of the way in which such information services are geared to the national system of library and information services. Their efficiency depends very largely, in fact, on the way in which Government policy and practice maintain an adequate national system. A National Science Centre, a National Lending Library for Science and Technology and a National Reference Library in that field, as well as an adequate regional system, are vital factors, and appear to have been completely overlooked by the Select Committee.

As regards the financial recoveries by the establishments for work done for industry, the Select Committee on Estimates recognizes that these necessarily vary widely with different conditions, from 95·4 per cent for the Fire Research Station, which is a joint enterprise between the Department and the Fire Offices Committee, which bears half the cost of the Station, to as little as 0·3 per cent for the Radio Research Laboratory, which works mainly for Government departments. Any increased rate of recovery for this Laboratory, the Pest Infestation Laboratory, the Road Research Laboratory and the Water Pollution Research Laboratory accordingly is likely to be at the expense of another Government department; nor does the new work of the Fuel Research Station promise to offer much opportunity for recovering any substantial part of the cost, in any event for the present. On the other hand, the Committee considers that the recovery rates of the Food Investigation Organization (3·4 per cent), the Mechanical Engineering Research Laboratory (5·9 per cent) and the Building Research Station (6·5 per cent) are much too low. It regards the new scales of charges to industry which the Department has recently prescribed for the three stations as satisfactory and likely to lead to some improvement in the rate of recovery; but it recommends that all three stations should approach the question with greater determination to achieve the best possible rate consistent with departmental policy, and in particular that the Building Research Station should take account of the benefits which a supplying industry may receive when research connected with its products is successfully undertaken.

One further recommendation in this context is prompted by the measurements which the Building Research Station is making of the effect on the Bakerloo tunnel of removing and replacing the earth cover while the new Shell building in London is being constructed. This work is of great value to the Department in connexion with its study on tunnels and also to the Shell Co., in that it is helping to reduce the risk of damage to the tunnel. The Estimates Committee recommends that in future, where it seems possible that any work carried out by the Department for its own purposes may incidentally result in direct advantage to an individual firm, an agreement should be negotiated with the firm concerned before the work is started, whereby the firm should pay a direct contribution to the costs, if in fact the firm obtains a direct advantage as a result of the work.

---

* Fifth Report from the Select Committee on Estimates together with part of the Minutes of the Evidence taken before Sub-Committee B and Appendices, Session 1957–58—The Department of Scientific and Industrial Research. Pp. xvi+165. (London: H.M. Stationery Office, 1958.) 9s. net.

These recommendations of the Estimates Committee, and those already mentioned (*Nature*, October 25) in dealing with the relation of the Department of Scientific and Industrial Research with other Government Departments, have far-reaching implications which are not discussed in the report, and it seems doubtful whether the Committee fully appreciates the import of some of its proposals. It is at least arguable whether the Committee's approach to the whole question of receipts for work done by the Department is sound. It seems to ignore the question of national advantage, and to overlook the fact that research is a resource and not simply an investment. The returns, moreover, are not to be reckoned in financial terms, and while, on the evidence submitted to the Committee, it is probable that some of the establishments of the Department might make firmer efforts to secure some greater return when work has been carried out for the benefit of a particular institution, firm or department, it is at least dubious whether that should be a prime consideration in research policy.

In the first place, the instructions recommended by the Committee are likely to lead to unnecessary delay in carrying out a research programme which the Department wishes to implement for its own purposes ; agreements are unlikely to be negotiated readily or quickly, particularly if the benefits are intangible or a long way ahead. Secondly, the outlook which the Estimates Committee seeks to foster could easily distort the balance of research carried out by the Department by encouraging concentration on *ad hoc* or sponsored investigations and inquiries rather than on the long-range investigations which should be a prime purpose in a central research organization. Apart from this, it overlooks the educational value of the Department's research stations in encouraging research in industry. Excessive concentration on the financial side could easily hinder the attempt which the Department is making to foster a spirit of research and co-operation with industry, and it also ignores the fact that the benefits which accrue from the Department's successful investigations are in fact returns to the nation as a whole and part of the justification of its investment.

The very fact that the work of the Department has been submitted to this searching inquiry by the Estimates Committee points to the need for some satisfactory means of setting forth, both to Parliament and to the general public, a clear and balanced picture of the work of the Department as a whole, and its significance both for the national economy and public welfare. For all the shrewd comments in this report, it appears to have escaped the Select Committee that this problem is still unsolved. Again, while the minutes of evidence contain much that deserves to be noted and weighed by the scientist and by those concerned with the organization of the nation's scientific and technical effort, the Estimates Committee, even when due regard is had to the limits of its terms of reference, seems to have been guided by too narrow a conception of efficiency as applied to scientific and technological effort.

The efficient use of the limited resources in Britain of scientific and technological man-power, which is the decisive factor in that effort, depends on the wise selection of objectives and, as the Estimates Committee recognizes, on the appropriate termination of projects and programmes, though this may well be less a financial or economic decision than it appears to indicate. It depends no less, however, on the ability to attract men of the highest calibre ; it also depends on the conditions under which they are required to serve, so that there is neither waste of highly trained man-power on work which could be equally well performed by less highly trained men nor uneconomic use of highly expensive equipment. Some of the Committee's recommendations seem likely to discourage recruitment of staff of the requisite calibre, and to lead to expensive equipment being insufficiently used. Certainly they are unlikely to encourage the maximum use of such equipment.

Nevertheless, the comments should prompt a further and widespread discussion of the whole structure and balance of the nation's research effort, and its disposition between Government establishments, universities and industry. It provides an opportunity which should be used by professional bodies as well as by Parliament, not merely to ensure that the administrative structure is appropriate and effective, but also that the ancillary factors contributing to the effective use of the scientific and technological effort of Britain, as well as to the efficiency with which that effort is conducted, receive adequate attention and support. It is probably at that point above all that additional financial support could bring the biggest increase in the return from the national effort in research and development at the present time. The Estimates Committee's report may well direct further attention to such matters of organization as the departmental organization of research in relation to a general or central body such as the Department of Scientific and Industrial Research ; but it is this question of the contributory factors on which attention needs to be focused.

FLUID MOTION IN NATURE

Natural Aerodynamics

By Dr. R. S. Scorer. (International Series of Monographs on Aeronautical Sciences and Space Flight. Division 2 : Aerodynamics, Vol. 1.) Pp. xi+312+22 plates. (London and New York : Pergamon Press, 1958.) 60*s*. net.

THE unusual title of this book is easily explained. Dr. Scorer writes about those motions of real fluids which arise chiefly as a result of solar heating and topography. The book is not concerned with the central problem of ordinary aerodynamics, the calculation of the forces experienced by bodies of prescribed shape moving through the air, but is an account of winds, convection currents, air waves, clouds and rain, and thus comprises a selection of topics from both dynamical and physical meteorology.

In the opening chapters, which deal with the equations of hydrodynamics and the concepts of vorticity and viscosity, the treatment might fairly be described as 'popular', in that much of the account is in plain language and no excessive demands are made upon the reader's knowledge of mathematical techniques. The later chapters, which deal with specific problems, require a firm grip of applied mathematics for their understanding; but the book is addressed more to the physicist and meteorologist than the mathematical specialist, and the author evidently has decided that for his purpose physical ideas are more important than details of mathematical manipulation. The result is an unorthodox but lively text, for Dr. Scorer never hesitates to interpose philosophical arguments whenever an opportunity presents itself.

The first six chapters summarize the equations of fluid motion, the Coriolis effect, vorticity, viscosity, boundary layers, wakes and turbulence. The discussion of such matters in about 140 pages implies considerable condensation, and at least one theorem concerning circulation is stated incorrectly in its abbreviated form (p. 59). However, the average physicist and perhaps even the specialist in fluid motion can scarcely fail to gain some new insight into the ways of fluids from a perusal of these vigorously written chapters (especially that dealing with vorticity), although there are dangers of over-simplification, as in the facile definition of turbulence as "a kind of stirring motion by which anything possessed by air is diffused" (p. 124). This section of the book is a useful introduction to a subject which tends rather easily to become a preserve of mathematicians, and it is refreshing to be reminded that at times even the hypothetical ideal fluid of the classical hydrodynamics has affinities with air and water.

The real originality of the book and, in the reviewer's opinion, its main value, lies in Chapters 7–10, which deal with matters which, for the most part, have not yet found their way into the curricula of the universities, although their importance in many fields of applied science is manifest. Natural or buoyant convection usually gets little more than a brief reference in text-books, and then on a qualitative rather than a quantitative basis. Dr. Scorer's account of convection is primarily mathematical, but the practical application is well illustrated by examples from meteorology (cumulus clouds), gliding, and the behaviour of hot plumes from industrial stacks. The chapter on air waves ranges from explosions to lee waves set up by mountains, a topic on which Dr. Scorer is especially well qualified to write. The account of the formation of clouds and of precipitation is mainly descriptive, which is to be expected in view of the varied and highly complicated physical processes involved. In the final chapter, entitled "Philosophy of Method", Dr. Scorer manages to combine an account of the methods of dimensions and of small perturbations with a frontal attack on geographers.

The book is thus an original account of some parts of mathematical physics mingled with the author's highly individualistic views on science in general. For such a wide field, the serious student may consider the treatment too superficial; the general reader, on the other hand, may be hard pressed at times to find his way through a juxtaposition of description and calculation. But Dr. Scorer has succeeded in writing a book which is often illuminating and never dull, and in its pages he has brought together much material which hitherto has existed only in scientific journals. There is nothing quite like this book in meteorological literature, and it is to be hoped that its high price will not deter those who wish to learn about the modern approach to some of the most fascinating and important problems of meteorology.

O. G. SUTTON

MULTIVARIATE ANALYSIS

An Introduction to Multivariate Statistical Analysis

By Prof. T. W. Anderson. (Wiley Publications in Mathematical Statistics.) Pp. xii+374. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.) 100s. net.

Some Aspects of Multivariate Analysis

By Prof. S. N. Roy. (Indian Statistical Series, No. 1.) Pp. viii+214. (New York: John Wiley and Sons, Inc.; Calcutta: Indian Statistical Institute; London: Chapman and Hall, Ltd., 1957.) 64s. net.

The Analysis of Multiple Time-Series

By M. H. Quenouille. (Griffin's Statistical Monographs and Courses, No. 1.) Pp. 105. (London: Charles Griffin and Co., Ltd., 1957.) 24s.

THESE three books do indeed possess the common property of containing subject-matter falling under the general heading of 'multivariate analysis', but they differ greatly, both in content and intent, among themselves. They are arranged, above, in order of a marked increase in specialization. Prof. Anderson's book is intended for the advanced college student, and has—among other desirable text-book features—a clear and thorough manner of exposition, examples in the text, and an ample supply of problems (but no model solutions). Prof. Roy's book describes a number of special topics in multivariate analysis to which he has applied some original ideas on the construction of tests and confidence intervals. This book is really a rather loosely connected series of monographs, technically of a rather advanced nature, requiring a good deal of previous reading for full appreciation, but yielding rewards in stimulation and interest. In the last book of the trio, Quenouille gives detailed consideration, accompanied by many numerical illustrations, to the application of more or less standard statistical techniques in one specific field—that of time series in which, at each epoch, observations are made on more than one variable.

Were it not for considerations of price, it would be expected that Prof. Anderson's would prove to be the most widely used of the three books. It provides, for the first time, a work suitable for the student wishing to obtain a sound appreciation of the whole field of multivariate analysis. Careful study of this book should leave few gaps to be filled—apart from those created by the present flow of papers on this subject. The first four chapters contain fundamental results in statistical theory, with special bias towards multiple regression, and give the reader an opportunity to become accustomed to the habitual use of matrices and the consequent slightly unfamiliar appearance of the text. The next chapters are on the generalized (Hotelling's) T^2 statistic, on the important 'classification problem' (also known as 'discriminatory analysis'), and on the (Wishart) joint distribution of variances and covariances. These are followed by an important chapter on multivariate extensions of the general linear hypothesis, or 'generalized analysis of variance', and two chapters on special applications of these results. Chapter 11 is on analysis into principal components, on the lines developed by Hotelling. Chapters 12 and 13 introduce the ideas of canonical correlations and variables, and the associated problem of finding the joint distribution of the characteristic roots of a certain matrix. There is a brief concluding chapter outlining various special topics in multivariate analysis.

Prof. Roy's book effectively takes as its starting point the latter part—Chapters 12 and 13 especially—of Prof. Anderson's book. Roy's method of test construction leads to criteria based on the greatest and the least of the characteristic roots of a certain matrix, rather than the symmetric functions of these roots which are usually encountered in the more conventional methods of approach. Roy is able to show that the tests he proposes should be reasonably sensitive, but he does not compare, directly, the powers of competing tests in any particular case. Indeed, numerical illustration is notably lacking, and even significance limits for the new criteria are not given, although some have been computed. In this book there will also be found (*a*) the construction of sets of 'simultaneous confidence intervals' for a number of parameters, with joint confidence coefficient defined as the probability that every one of the confidence intervals contains the true value of its appropriate parameter, and (*b*) analysis of multiple contingency tables (described as 'non-parametric generalizations of analysis of variance and multivariate analysis'). The omission of numerical illustration avoids directing attention, in (*a*), to the fact that the strong condition required of the confidence coefficient must often be paid for by uncomfortably wide confidence intervals. About one-third of the book is occupied by nine appendixes containing mathematical results used in the main text.

Quenouille summarizes the problems considered in his monograph as follows (slightly abbreviating the original): (1) Definition of the structure of several interdependent time series, and deduction therefrom of their properties. (2) Inference of structure from population, or from observed, correlation properties. (3) Likely errors in specification of structure, and the effects of these errors on analysis. (4) Methods of estimating values of parameters, given a particular structure, and of testing whether a particular structure is appropriate. (5) Practical application of techniques derived from study of the above problems to observed series.

The programme so specified is carried out in a competent manner. There does not seem to be any attempt to make the treatment or discussion exhaustive—for example, the work of Rudra on the problem of discriminating between rival structures in the case of univariate series is not mentioned—but the author has produced an adequate text for anyone wishing to extend a moderate knowledge of univariate time series analysis into the multivariate field. The text is written with evident regard for students' difficulties, and numerical illustration is profusely provided. The omission of any reference to periodic series and periodogram analysis is unfortunate, since it is a rather sweeping assumption to suppose that all observed series may be usefully assigned a moving average or autoregressive structure, with which the monograph is largely preoccupied. A list of symbols, with meanings, is provided. Exception can be taken to the author's statement that E is the usual symbol for the operator with the property:

$$Ex_t = x_{t-1}$$

—this operator would usually be written E^{-1}.

Both Roy's and Quenouille's works suffer from a number of small misprints, mostly in suffixes, exponents, and similar positions. They are not likely to prove misleading to the informed reader, though the occurrence of a subscript $t - 1$ instead of $t + 1$ in Quenouille's equation (5.6.1) could cause some puzzlement.

The essential qualities of the three books are, briefly: Anderson: a sound text-book of traditional style in a new field; well produced, but expensive for its size. Roy: a book for the specialist—and only for a very special kind of specialist; consolidates material at present scattered in the literature, and may stimulate some further research. Quenouille: a readable book, repaying the effort of understanding the rather unusual notation; coverage of subject rather uneven, but not unduly so for a fresh subject.

N. L. JOHNSON

EIGENFUNCTIONS

Eigenfunction Expansions Associated with Second-Order Differential Equations, Part 2

By Prof. E. C. Titchmarsh. Pp. xi+404. (Oxford: Clarendon Press; London: Oxford University Press, 1958.) 70*s*. net.

IN 1946, Prof. Titchmarsh published "Eigenfunction Expansions associated with Second-Order Differential Equations" (Oxford, at the Clarendon Press) and a photographic reprint was made in 1950. This slim and modest volume contained the results of Titchmarsh's researches from 1939 until 1945 and provided a new and original theory of this important and growing subject, which was applicable not merely to equations of the Sturm–Liouville type, but also to the singular equations studied by Weyl.

Titchmarsh's method is independent of the calculus of variations, of the theory of integral equations and of the theory of linear operators—each of which has been used as a basis of the theory of eigenfunctions of differential equations. Titchmarsh had discovered a simple and direct method of studying this subject by means of contour integration and the calculus of residues, and of proving the central expansion theorem. In the present volume this method is extended to *partial* differential equations of the form:

$$\Delta\psi + \{\lambda - q(x,y, \ldots)\}\,\psi = 0$$

where Δ is the Laplacian operator in n-dimensional Euclidean space.

The principal problems discussed are (1) the expansion of an arbitrary function in terms of the eigenfunctions of a prescribed equation, (2) the effect of small changes in the equation on the eigenvalues and eigenfunctions, (3) the nature of the spectrum and the distribution of the eigenvalues. In addition to these great questions, the author also considers a number of special problems of considerable interest, namely, the eigenvalues of separable equations, and the case in which the function $q(x,y, \ldots)$ is periodic. The final chapter deals with the analytical apparatus which has been used in the body of the work and provides proofs for the various theorems which have been required.

Many of these problems are of considerable interest to mathematical physicists, especially to those working in quantum theory, and plausible but non-rigorous treatments are well known. Titchmarsh has succeeded in giving rigorous proofs and has put all quantum theorists heavily in his debt by his careful analysis of the complex and difficult questions of eigenfunction theory. His investigations of the expansion theory, the perturbation theory and the spectral theory are each of significance for the applied mathematician and, if not every proof can be described as short and simple, they are all admirably lucid and cogent. G. TEMPLE

ELECTROCHEMISTRY

Electrochemistry

Principles and Applications. By Dr. Edmund C. Potter. Pp. xii+418. (London: Cleaver-Hume Press, Ltd., 1956.) 50s.

THE author states that his aim was to produce a concise introductory text for the technological student and the specialist electrochemist in which he would endeavour to reflect the modern emphasis on a more dynamic and mechanistic interpretation of electrolytic processes than, presumably, has hitherto been the case.

To write a book which would be of service to the beginner and the specialist alike would, indeed, be an accomplishment, and this the author has certainly not achieved. This book is more likely to be of use to the student who has already gained a grasp of the fundamentals of electrochemistry from the standard works on physical chemistry, and who wishes to acquaint himself with the industrial applications of the subject.

The mechanistic interpretation of electrolytic processes refers essentially to the interpretation of the dependence of hydrogen overpotential on current density. This has been included in text-books which have been published within the past twenty years.

Regarding the chapters dealing with fundamentals, the logical development and presentation often leave much to be desired: the English is not always good and the sentences are often involved and obscure. It is likely that the text was based on rather sketchy lecture notes, for it lacks much of that explanatory matter which a lecturer must expound but which the student may not then think it worth while to record.

The treatment of the Arrhenius, activity and Debye and Hückel theories is so cursory that a student would not be able to glean anything very substantial from it. Throughout, the term 'activity' is applied to ions, but the author does not indicate that the activity theory has only been satisfactorily applied to the electrolytes contained in 'cells without transport'. One such cell is described, but advantage was not taken to show how it might be used to determine experimentally the mean ionic activity of an electrolyte, for example, $a_{\pm HCl}$.

It is somewhat disturbing to read on p. 83 that "Nernst's original arbitrary zero of potential is that potential corresponding to the reversible equilibrium between hydrogen gas at one standard atmosphere pressure and hydrogen ions at unit activity". In 1900 Nernst stipulated that the electrode solution should contain hydrogen ions at unit concentration, and it was not until 1913 that G. N. Lewis advocated the substitution of activity for concentration. Dr. Potter does not explain that the activity of a single ion cannot be determined experimentally and that it is necessary to assume that, for example, for hydrochloric acid, $a_{\pm HCl}$, is equal to a_H. Instead, he merely states that "If the electrolyte used is hydrochloric acid a strength of approximately 1·2 *N* at 25° C. corresponds to unit activity of hydrogen ions", and he gives no clue how such a concentration has been experimentally ascertained.

The misuse of the terms 'strength', 'strong' and 'weak' in referring to solutions and current is to be deplored, for chemistry teachers have, for many years past, been deprecating the use of 'strength' as being synonymous with 'concentration', and 'current' (a rate) as being synonymous with 'electricity' (a quantity). Such phrases as "electric current flows" (p. 1) and "passage of current for 1 second" are particularly objectionable. Many of the conductometric titration curves depicted are defective, and especially that for phosphoric acid. In defining 'acids' and 'bases' in terms of the Lowry–Brønsted theory, 'hydrogen ions' should read 'protons'. The method of deriving expressions for electrode potentials can scarcely be adapted to the electrodes in a cell with transport.

Though by no means a complete survey of electrochemistry, the last half of the book is obviously that part of the subject with which the author is more intimately conversant and it brings together a good deal of useful material. H. T. S. BRITTON

NEOMYCIN

Neomycin

Its Nature and Practical Application. Edited by Selman A. Waksman. Pp. x+412. (London: Baillière, Tindall and Cox, Ltd., 1958. Published for the Institute of Microbiology, Rutgers University.) 40s.

THE comprehensive screening programme to which the Actinomycetes, and in particular the members of the genus *Streptomyces*, have been subjected in various laboratories has provided many new antibiotics, a number of which are of value in chemotherapy. As a result of such a programme, Waksman and Lechevalier in 1949 announced the discovery of a new basic antibiotic which was named 'neomycin'. It was active against bacteria resistant to streptomycin, including tuberculosis organisms. It was thought that the new antibiotic might have all the desirable properties of streptomycin without its disadvantages, and that it could find an important place in tuberculosis therapy. Unfortunately, the high hopes at first entertained of neomycin were not fulfilled in practice, since clinical trials showed that when administered parenterally it had an irreversible injurious effect on the auditory system. Neomycin has, however, gradually established itself, in spite of its limitations, as a useful antibiotic and indeed the drug of choice in certain infections.

As commercially prepared, neomycin is a mixture of two isomeric compounds, neomycin *B* and neomycin *C*, in which the former predominates. Although the molecular structure of neomycin is not yet completely established, sufficient is known to place it as closely related to streptomycin, from which, however, it differs considerably in biological properties. It has a wider antibacterial spectrum than any other antibiotic, is rapid in action, shows little tendency to produce resistant organisms and rarely produces hypersensitivity in the patient. Its disadvantages, the tendency to produce deafness and renal damage, are only evident when it is administered parenterally. It is one of the best antibiotics for local use and as an intestinal antiseptic by the oral route since it is not readily absorbed from the bowel.

The present work, appropriately under the editorship of Dr. Selman A. Waksman, offers a timely account of the information at present available, mainly from American sources, concerning the nature, microbiological aspects, pharmacological properties, and clinical and veterinary uses of neomycin. It is a compilation resulting from a co-operative effort to assemble between the covers of one volume the knowledge and experience of a number of investigators from different centres in the United States. Each chapter is written by one or more of these contributors, but due, no doubt, to careful planning and skilled editing there is little overlap, and the result is a balanced and most readable account of the present state of knowledge on the subject of neomycin, which could hitherto be assessed only by tedious search of the literature.

There is an excellent bibliography in which the references are sensibly collected together instead of being distributed at the end of each chapter (apart from a few supplementaries). Appendixes summarize the specific clinical uses of neomycin and list the preparations containing neomycin with their trade names and indications, compiled from information supplied by the various manufacturing companies, the names and addresses of which are given. This list may serve to correct the impression, which might otherwise be gained from reading the book, that streptomycin is of little interest outside the United States, since the number of foreign manufacturers cited is nearly twice that of firms located in the United States. A THERMOPHILOUS SHRIMP FROM TUNISIA

Anatomie und Histologie von *Thermosbaena mirabilis*
Ein Beitrag zur Phylogenie der Reihe Pancarida (Thermosbaenacea). By Dr. Rolf Siewing. 1958. *Akademie der Wissenschaften und der Literatur. Abh. Math.-Naturw. Kl. Jahrgang* 1957, No. 7: 197–270, 43 text-figs.

Dr. Siewing's recent admirable studies on the comparative morphology of the Crustacea Malacostraca have been widely acclaimed and no one is better qualified than he to elucidate the anatomy and histology of *Thermosbaena mirabilis* Monod. This minute crustacean, first described in 1924, is restricted in its distribution to a few baths, fed by hot springs, at El Hamma, Tunisia. In recent years three subterranean species, belonging to the closely related genus *Monodella*, have been found in Italy and Yugoslavia. These four species, measuring 1·5–4 mm. in length, are unique among Malacostraca in having a dorsal brood chamber formed by a temporary enlargement of the carapace. Opinion has varied as to the systematic position of the order Thermosbaenacea; it is sometimes referred to the division Peracarida, or placed between the Peracarida and the Syncarida; Sars united it with the Bathynellacea in a new group, the Anomostraca.

The material studied was collected by Dr. Anton Brunn in 1938. A detailed account, accompanied by admirably clear line drawings and microphotographs, is given of each system in turn—vascular, respiratory, nervous, digestive and reproductive. The reconstructions of the general anatomy of male and female are excellent, although an enlargement of the head end of Fig. 1, *A*, with its numerous guide lines, might with advantage have been included. Anatomical peculiarities are fewer than might have been expected. The oviduct opens in the usual Malacostracan position, at the base of the sixth thoracic limb, and there is no dorsally directed branch such as has been claimed for *Monodella* but not confirmed. Prof. Barker, who collected ovigerous females in September 1950, thinks that during oviposition *Thermosbaena* lies on its back so that the few large eggs drop into the brood chamber (personal communication). A pair of reduced, though possibly still functional, eyes has been found. Certain features appear to be adaptive, since they are paralleled in other minute cavernicolous or interstitial forms. For example, the extremely short heart is restricted to the first thoracic segment, where it is in intimate association with the respiratory carapace; in the Bathynellacea, which have no carapace, it lies in the fourth thoracic segment.

An appraisal of the external morphology follows. At times the author is prolix; for example, his interesting point about the segmentation of the thoracic limbs could have been made in a few paragraphs instead of in a few pages. In the second pair, which are set quite differently on the body and are apparently modified as gnathopods, the ischium has fused completely with the basis. In each of the succeeding limbs (peraeopods) it has almost completely fused with the merus. He concludes that the Thermosbaenacea, though closely related to, must be excluded from, the Peracarida. I am not entirely convinced of the necessity for the new division Pancarida, which is based chiefly on two characters: the structure of the maxillipeds and the dorsal brood chamber. The retention of two endites and the persistence, in some species of *Monodella*, of exopodite and/or endopodite in the maxilliped suggest, he says, a very primitive position for the Thermosbaenacea. This condition is widespread in the Decapoda and—the coxal endite apart—in Mysidacea. In *Monodella*, when both rami persist the maxilliped exhibits marked sexual dimorphism, the endopodite being modified to form a clasping organ in the adult male. As to the brood chamber: within the Copepoda certain parasitic forms have abandoned the normal method of carrying the eggs in favour of a carapacial brood chamber, and this has probably occurred independently more than once. Why then is the author so certain that something analogous could not have happened within the Peracarida (pp. 261–263)? There might be some good reason why, in a minute animal adapted to an extreme biotope, a ventral marsupium composed of oostegites became impracticable (for example, the thoracic limbs might be too short). Owing to the high temperature to which *Thermosbaena* has become adapted (around 45° C.) its feeding and locomotor habits would have to be studied in the field. This could only be undertaken by a competent observer who, from previous experience with other minute crustaceans, knew exactly which methods to adopt.

Whether one accepts his conclusions or not, Dr. Siewing is to be congratulated on another excellent piece of research. Isabella Gordon

Geophysics and the IGY

Proceedings of the Symposium at the Opening of the International Geophysical Year. Conducted by the United States National Committee for the International Geophysical Year, National Academy of Sciences, Washington, D.C., June 28–29, 1957. Edited by Hugh Odishaw and Stanley Ruttenberg. Pp. iv+210. (Geophysical Monograph No. 2.) (Washington, D.C.: American Geophysical Union of the National Academy of Sciences—National Research Council, 1958.) 8 dollars.

In the whole of the programme for the International Geophysical Year nothing has captured the popular imagination more than the attempts to explore the upper atmosphere. It is likely that the layman does not entirely appreciate the scientific significance of all the *Sputniks* and 'Black Knights' that leave the surface of the Earth; but he is certainly made more aware of this aspect of the International Geophysical Year, via the writings in the press, than of any other; and, in a way, so it is for the geophysicist.

Almost three-quarters of the space available in this monograph on the International Geophysical Year is devoted to the physics of the upper atmosphere. Eighteen papers cover most aspects of this science from 'whistler' (audio-frequency radio waves arising from lightning discharges) studies to auroræ observations; and, of these, five concern the use of rockets and satellites in this high-atmosphere work. The papers in this section which are of most interest to the general scientists are probably those dealing with the observations to be made on the geomagnetic field. A detailed knowledge of the Earth's magnetic field is of practical importance in many forms of science and their related applications, from ionospheric and auroral physics to navigation and mineral exploration.

There are twelve papers in the more solid side of geophysics: that is, the lower atmosphere and the Earth itself. These deal with meteorological and oceanographic studies, the polar work that has been and will be performed, and with information concerning the shape, crust, and mantle of the Earth via gravitational and seismological measurements.

This book is the outcome of a symposium held last year before the main programme began. As such, of course, much of the information contained in it is conjectural and, at this stage, out of date. However, it is worthy of consideration by anyone interested in the doings of the International Geophysical Year.

D. Taylor Smith

Quantitative Organic Analysis

By James S. Fritz and George S. Hammond. Pp. xiv+303. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1957.) 52*s*. net.

The contents of this book are more accurately described by a subtitle ("The Use of Fundamental Principles for Solving Problems in Organic Analysis") than by its main title. The latter would lead one to expect the book to start with the usual description of elemental analysis, but this comes nearly half-way through. Instead, the opening chapter is an interesting discussion of the difficulties arising in the determination of carbonyl groups by oximation, which is taken as an illustration of the problems encountered in devising schemes for determining functional groups in general.

Other chapters deal with acid–base titrations in non-aqueous solvents, indirect acid–base methods, oxidative and reductive methods, manometric methods, metal ion complexes, kinetics in analysis, spectrophotometric methods, separations, and physical and polarographic methods. Finally, there are useful hints on solving new problems and details for certain standard procedures, such as determination of hydroxyl groups by acetylation, saponification of esters, and determination of sulphur, of unsaturation by bromination, and of peroxides.

This is not a text-book in the ordinary sense; rather does it discuss the underlying principles of various methods and their advantages and limitations. Although it mentions many applications, experimental details are usually rather too brief for practical purposes. For example, the ordinary 'combustion' method is described, but the diagram of the tube gives no indication of the dimensions in spite of the mention of the 'micro-scale'; and the statement that "Glucose has been determined by oxidation with iodine to gluconic acid" gives no hint of the effect of such factors as alkalinity, concentration and time. Also, under distillation, theoretical plates are mentioned but not defined. The section on chromatography is not up to date, and too cursory.

In spite of these few minor blemishes (and of the spelling of Tollens without his 's'), the book is well worth reading, for it is clearly written and gives a fascinating review of the great diversity in analytical methods now available to the organic chemist; moreover, it is very well produced.

A. D. Mitchell

Dynamic Programming

By Richard Bellman. Pp. xxv+342. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1957.) 42*s*. net.

Many will have had glimpses over recent years of the work of R. Bellman in the field of multi-stage decision processes. Gradually, a body of concepts and methods has emerged for treating the many real problems that arise in this field. The developments to date have been collected and presented in the book under review, which is a Rand Corporation Research Study. The author begins with a chapter entitled "A Multi-Stage Allocation Process". This explains the type of practical situation to which the theory of dynamic programming relates and introduces the reader to the methods of solution. The next chapter adds a stochastic element to the problem of decision on a multi-stage process. The mathematical technique is developed in the next two chapters, and then follow three chapters on inventory and bottleneck problems. A chapter on multi-stage games is followed by a final chapter on Markovian decision processes.

This book, while very well written, is definitely an advanced text for the mathematician who is interested in the development and application of mathematical methods in management science, including econometrics. It will not be understood by most managers, but this may well be the result of our present social organization rather than a reflexion upon the author. It is not, after all, possible to convey highly technical concepts in a language that everyone can understand. The present book is an excellent example of the way in which mathematics is finding new domains of application, and for the first time clears the way for logical analysis of some time-worn riddles faced by business men. L. S. Goddard

CYTOPLASM IN SEXUAL REPRODUCTION

By PROF. KENNETH MATHER, C.B.E., F.R.S., and DR. JOHN L. JINKS

Agricultural Research Council Unit of Biometrical Genetics, Department of Genetics, University of Birmingham

GENETICAL studies have displayed the cytoplasm as playing but a minor part in the determination of differences among individual plants and animals produced by the sexual process. Evidently the cytoplasm handed on by a mother to her sexual offspring must be closely similar to that which she herself received from her parents in respect of any essential determinants of cell character and development. At the same time, there is every reason to believe that differentiation within an individual depends characteristically on change of the cytoplasm[1-3]. Thus, either the cell-lineage connecting the original zygotic cell of the individual with the egg it ultimately produces must be exceptional in involving no change of cytoplasmic type, or its cytoplasmic progression must come full circle within the individual, the end-point being the same as the beginning[1]. In higher animals there is no simple breeding test available for investigating the progression of a cell-lineage, of recognizing and separating progressive changes in nucleus and cytoplasm, by simple breeding; and even in higher plants this approach has yet to be put to successful use. Experimental intervention by the transfer of nuclei from cells at one stage to the cytoplasm of cells at another has been successfully practised and has yielded valuable results[4,5]. The implications of these findings are, however, as yet by no means fully clear[3], and in any event this technique is so demanding as to place sharp limitations on its use.

Micro-organisms present more tractable material, and the filamentous fungi in particular offer a certain, if limited, range of differentiation combined with the opportunity to propagate and breed from several types of cell in such a way that changes of the cytoplasm and nucleus can not only be detected but also distinguished from one another by reassociation of these cell parts. Thus, *Aspergillus glaucus*, for example, can readily be propagated in three ways: from the tips of the hyphæ, from the single-celled asexual spores termed conidia, and from the sexually produced ascospores. Propagation by any of these means produces an individual potentially capable of displaying the complete range of development, so that its capabilities may be fully observed and change from those of its parent recorded. Furthermore, the occurrence of anastomoses between hyphæ of different individuals, and the heterokaryosis to which this prospectively leads, allow of the bringing together of unlike cytoplasms as well as nuclei within a single individual, and of their sorting out and reassociation in both the conidia and the ascospores which that individual produces. Indeed, the conidia are especially valuable in distinguishing cytoplasmic from nuclear differences, for the nuclei of a heterokaryon normally sort out as units in the production of its conidia, without any of the genic recombination seen in ascospores. Thus, each kind of nucleus can be marked and followed unambiguously in conidial production by a single mutant gene.

Making use of these properties of the fungus, Jinks has been able to show not only that differentiation and ageing of the cells involve characteristic changes of the cytoplasm[6], but also that selection can be used to produce changes of character which spring wholly from alterations in cytoplasmic content[7]. Certain of these changes depend on differences among cells of like status, as where a sample of conidia from an individual produce offspring differing in their rates of growth so that selection may be practised among them. Others, however, appear to depend on cytoplasmic differences arising as part of the process of differentiation. Thus, if propagation is continued for several generations by conidia, the production of perithecia and ascospores gradually falls until the fungus at length loses its capacity for sexual reproduction and becomes imperfect[8]. If propagation is continually by hyphal tips, the capacity for sexual reproduction is similarly lost, but so later is that for the production of conidia also. This has also been observed in *Neurospora*[9]. Similar changes can, of course, come about by the change of nuclear genes within an individual; but these are spasmodic and show all the unpredictability of gene mutation, whereas the cytoplasmic alterations appear as characteristic of the normal processes of differentiation and development.

So far, these changes have shown us no more than the negative side of differentiation, for they all depend on the loss of a capacity which is no longer being used and which is therefore no longer of importance to the plant. If propagation is wholly by conidia, the production of sexual structures is of no significance and its loss of no disadvantage. Indeed, its retention could be actively disadvantageous by the profitless consumption of nutrients and metabolic materials capable of more useful deployment elsewhere, and it is thus no surprise to find conidial production rising at first as that of ascospores declines. But hyphæ must obviously continue to be produced, as they are a necessary link between parent and daughter conidia. Where, on the other hand, propagation is wholly by hyphæ, neither conidium nor ascospore takes any obvious role in the cycle, so that both may be lost with impunity, at least in the short term. It would thus appear that only capacities essential to the operative reproductive cycle are retained, the cytoplasm changing so as to lose the ability for sustaining types of development no longer of significance to the plant.

When, however, we turn to the sexual cycle a different picture emerges. With continued sexual propagation, the production of conidia is of no more importance than was that of ascospores with conidial propagation—yet conidia are never lost as a result of sexual propagation, nor indeed is the frequency of their production reduced in any way so far as can be seen. In contrast to the asexual, therefore, the sexual cycle maintains in the cytoplasm the full range of developmental capacities even where these are no longer of significance. Furthermore, this does not merely reflect an absence of cytoplasmic change in the cell lineage connecting parent ascospore and daughter, as we can see if we go back to lines the

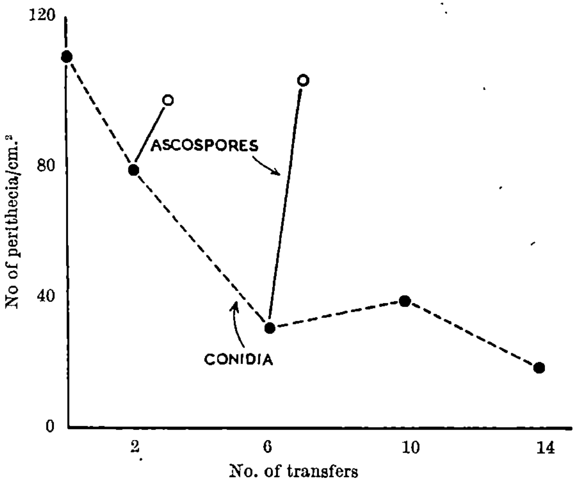

Fig. 1. The effects of propagation by conidia and by ascospores on the frequency of perithecial production in *Aspergillus glaucus*. Continued propagation by conidia (dotted line) results in a gradual decline of perithecial production. This is, however, immediately restored to its original level by a single propagation through an ascospore

sexual capacity of which has been reduced by conidial propagation. This reduction is gradual, but no matter how far it has gone, so long as any ascospore remains to be taken, the plant can be restored to complete, or virtually complete, sexuality by a single propagation through an ascospore (Fig. 1). Whether sexuality could be so restored to a plant which has completely lost its capacity for sexual reproduction is, of course, an unanswerable question since the necessary ascospore is not produced.

Thus, where a number of conidial propagations are interposed in the lineage between parent and daughter ascospores, the cytoplasm demonstrably changes in its determination of sexual capacity. It is, nevertheless, restored to its original state by the single propagation through the final ascospore. Evidently the process of sexual reproduction involves an active and positive re-adjustment of the cytoplasm, a 'spring-cleaning' or 're-tailoring', so that despite the alterations the standard basic cytoplasmic pattern is once again restored. There has been a cytoplasmic progression during the time of asexual propagation, but it is brought full circle during the process of sexual reproduction.

A further consequence of this re-standardizing effect of sexual reproduction on the cytoplasm is seen when the variation between individuals arising from ascospores is compared with that between individuals from the conidia of the same parent plant. Where the parent is a heterokaryon, genic segregation and recombination will occur in its sexual offspring. Their variation may thus be greater than that of conidial offspring, in the production of which only sorting-out of whole nuclei can occur. But if the parent is a homokaryon, carrying only one genetical type of nucleus, genically determined variation must be absent from all the offspring, whether sexual or asexual, and can indeed be shown to be absent by suitable tests. The variation is then found to be much greater among the conidial than among the sexual progeny (Fig. 2). In other words, the cytoplasm is more variable between the conidia than between the ascospores. Again we are seeing the standardizing effect of sexual reproduction on the cytoplasm.

Comparison of the effects of propagation by ascospores and conidia indicates an active re-standardization of the cytoplasm during the sexual process, though, of course, it does not tell us precisely where in the sexual cycle this occurs; further observation will be needed for that. Comparison of the effects of propagation by conidia and hyphal tips suggests that some readjustment of the cytoplasm may take place during conidial production, though it must obviously be less comprehensive and precise than that occurring in the sexual cycle. Continued propagation by hyphal tips results first in the decrease and loss of ascospore production, then in the decrease and loss of conidial production, and finally in a progressive difficulty even of the hyphæ to maintain full growth. So long, however, as conidia are produced the intervention of a conidial propagation will at least partly restore the capacity for conidial production, and it will improve hyphal growth itself. Furthermore, certain cytoplasmic adaptations, as for example to tolerance of mercuric chloride in the medium, though regularly transmitted via the hyphæ, are passed on much less regularly through conidia[10], and not at all through ascospores. Thus, the process of cytoplasmic re-standardization, though shown most characteristically and precisely by the sexual cycle, may not be confined to it.

Should sexual reproduction always involve a standardizing or cleaning of the cytoplasm, as it appears to do in *Aspergillus glaucus*, the cause of the cytoplasm's apparent inertness in hereditary transmission, as displayed by genetical experiments, would be clear. There is, however, as yet, little evidence from higher plants and animals to show whether such a process occurs or not. With some exceptions, chiefly in the Leguminoseae, plant virus infections are not transmitted through the seed. This suggests that the cytoplasm may be actively readjusted during egg-production, though the evidence cannot be regarded as compelling before it has been shown that the virus does actually enter the cell-lineages of the growing points from which the eggs are ultimately produced. We know also that the side-shoots of some plants show a type of growth different from that of the main shoot when both are taken as cuttings[11]. It would be of great interest to know how the two types behave in subsequent

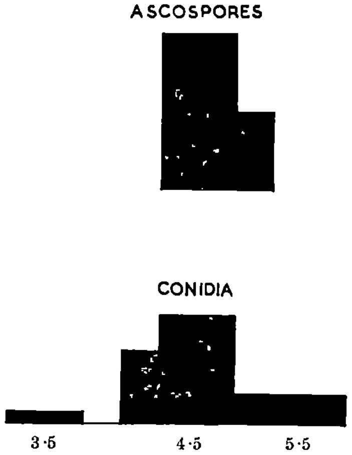

Fig. 2. Histograms to show the frequencies of colonies with different rates of growth among (above) the sexual and (below) the conidial progeny of a homokaryon of *Aspergillus glaucus*. The conidial progeny are more variable

breeding. In this way it would be possible to show first whether the difference itself involved nuclear change, and given that it did not, whether the cytoplasmic difference was abolished during sexual reproduction. By analogy with *Aspergillus*, we should expect the sexual offspring of both types of cutting to be like the original plant from which the cuttings were taken. There is evidence that the cytoplasm of parthenogenetic eggs in Rotifers can change with the age of the mother[12], and even that the cytoplasm can vary in the eggs of *Drosophila melanogaster*[13]; but the variation in the flies appears to be trivial, and in any event a relation to ageing does not preclude the occurrence of a process such as that detected in the fungus, since ageing of the egg could follow on a standardization of the cytoplasm during its initiation. In man, fraternal twins may be quantitatively more alike at birth than identicals. This can be interpreted as indicating that the cytoplasms of separately produced eggs are more alike than those of two totipotent cells produced from the division of a single egg[14], as might be expected if a process of cytoplasmic re-standardization occurs during human sexual reproduction.

Where, as in *Aspergillus*, a process of cytoplasmic standardization occurs as a regular feature of sexual reproduction, a remarkable comparison appears between nucleus and cytoplasm. Sexual reproduction is the time of nuclear variation, springing from recombination of the genes. Somatic development, on the other hand, is relatively a time of nuclear stability, for although nuclei may show changes during development, these are secondary and not the prime cause of differentiation. With the cytoplasm the situation is reversed. Somatic development and differentiation depends characteristically on cytoplasmic change, while sexual reproduction is the time of cytoplasmic stabilization or standardization. Sexual reproduction would then be providing not only the familiar means of achieving that redistribution of genes upon which adaptation ultimately depends, but also the means of supplying each new individual with a precisely adjusted cytoplasm in which those genes can successfully do their work of guiding its differentiation and development.

LOCALIZATION OF INTERACTION SITES IN MULTI-COMPONENT TRANSFER SYSTEMS: THEOREMS DERIVED FROM ANALOGUES

By Prof. BRITTON CHANCE, WILLIAM HOLMES and JOSEPH HIGGINS
Johnson Research Foundation, University of Pennsylvania, Philadelphia

AND

Dr. C. M. CONNELLY
Rockefeller Institute, New York City

A STRIKING phenomenon of electron transfer in oxidative phosphorylation systems is the change in the steady-state oxidation-reduction levels of the respiratory carriers in response to changes in the concentration of phosphate or phosphate acceptor[1]. When, in an adjacent pair of carriers, one component is observed to become more oxidized and the other more reduced, a crossover point is identified[2-3]. Depending upon the experimental conditions, three such points can be observed in the respiratory chain of mitochondria: between reduced pyridine nucleotide and flavoprotein, between cytochromes *b* and *c*, and between cytochromes *c* and *a*[1]. It has been of great importance to determine what relationship may exist between the position of these crossover points and the sites at which the chemical reactions occur that lead to energy conservation and finally to the phosphorylation of adenosine diphosphate.

Isolation of portions of the respiratory chain has not succeeded in identifying the location of sites of energy conservation because of the difficulty of isolating components of the chain[4], the loss of phosphorylative activity upon isolation[5], and the demonstrated changes in the pathways of electron transfer that may arise upon chemical fractionation of the components[6-8]. Thus, fractionation and reconstitution cannot yet be used for final proof of conclusions that are drawn from physical-chemical studies of the phosphorylative process.

At present, it is necessary to deduce the location of sites of energy conservation from a consideration of the response of a chain of electron-transferring enzymes to the presence or absence of an inhibitor that can act simultaneously at several sites in the chain. Such a multi-component system is difficult to comprehend without the derivation of general theorems concerning the response of such systems by mathematical procedures and by observations of the response of model systems or of analogue-computer representations of various mechanisms.

All phenomena associated with cross-over behaviour were first observed in direct studies of the respiratory enzymes of mitochondria, during which it became apparent that certain rules permitting the localization of phosphorylation sites might apply. The cross-over

behaviour of the chemical system has stimulated a number of studies to demonstrate generalities relating interaction sites to cross-over behaviour. The first study was made with an electronic analogue computer representative of the chemical system that operates in accordance with the law of mass action[2] and has led to some general rules summarized here. These rules, in their more elementary form[2], stimulated a mathematical approach involving inequalities applicable to many other types of mechanism[3]; this approach is presented in detail in another paper[9]. Holton[10 11] has recently used a current-flow network to demonstrate that interaction in physical as well as chemical systems can be located by the cross-over generalities given here. The more general applicability of these ideas justifies their detailed description.

Responses of the Respiratory Chain

Since spectroscopic observations of the response to adenosine diphosphate of isolated mitochondria and of mitochondria in intact cells and tissues are now extensive, a summary is appropriate (Table 1). In the course of these studies it was found that the appearance of a cross-over point depends, in specific cases, upon the balance of dehydrogenase and oxidase activities and, in general, upon relative values of reaction velocity constants for the interaction of the components of the respiratory chain. These velocity constants are affected by many factors, particularly the source of the mitochondria, the nature of the substrate, the presence of inhibitors, and the temperature. So that the data will conform with the results obtained from analogues discussed in the following paragraph, the responses are tabulated for decreases of flux caused by the exhaustion of adenosine diphosphate. A minus sign corresponds to a reduction, a plus sign to an oxidation, and a zero to no observable change (presumably the result of a balance of oxidizing and reducing tendencies). From the data of Table 1, we draw the following generalizations. (1) Only minus signs are observed for reduced pyridine nucleotide, and only plus signs are observed for cytochromes a and a_3 in isolated mitochondria. (2) The other components may show minuses, pluses, or zeros, depending upon the conditions. (3) Cross-over points (− to +, going from substrate to oxygen (see below)) localize interaction sites between reduced pyridine nucleotide and flavoprotein, b and $c + c_1$, and $c + c_1$ and a. Reversed cross-over points (+ to − (see below)) are found between flavoprotein and b. Since the resolution of the spectroscopic method is insufficient to distinguish accurately between cytochromes c and c_1, it is not known whether another cross-over point lies between these two components; however, thermodynamic considerations make this unlikely. In toad heart muscle, some preliminary evidence for a cross-over point between a_3 and oxygen has been obtained, but this is not supported by studies of the isolated toad heart mitochondria (Ramirez, J., personal communication). The three cross-over points localized thus far are consistent with the P to O value of the respiratory chain of approximately 3, although additional sites of phosphorylation are not ruled out by any existing data.

The data for intact cells, although less complete than those obtained for isolated mitochondria because of the inherent difficulties in controlling the type of substrate employed, show two of the three cross-over points observed in the isolated systems. This type of study should afford a basis for conclusions on the similarity between the phosphorylation efficiency of intact cells and that of isolated mitochondria.

Model Systems and Computers

In general, model systems are constructed for the purpose of representing a complex process on a convenient scale of size, time, etc. The model may represent accurately all the features of the original, or just some of them. In the latter case, the model may also demonstrate artefactual responses that must be carefully guarded against. The model may be constructed as an analogue of the process itself: for example, as a chemical system with simpler reactions or as an electric or hydraulic analogue where chemical concentrations are represented by voltages or liquid volume.

A more general approach is the computer solution of differential equations which represent the basic physical laws of the chemical system. This method has been used in studies of the respiratory chain and its associated phosphorylation reactions[3]. This model is based upon the assumption that the law of mass action applies to the reactions of the components of the respiratory chain[3]. On the basis of

Table 2. CROSS-OVER BEHAVIOUR OF ELECTRON-TRANSFER SYSTEM CAUSED BY DECREASES OF FLUX IN RESPONSE TO CHANGES IN INTERACTION AT THREE SITES

Enzyme concentration 10^{-6} *M*. Reaction velocity constants are specified in equations or in table in units of μmolar^{-1} sec.$^{-1}$. k_2, k_4, and k_6 are decreased from 0·9 to 0·09 μmolar^{-1} sec.$^{-1}$ to give the steady state concentration changes shown in units of 10^{-8} molar. Values for k_5 and k_9 are given in the table

$$\begin{tikzcd} S \arrow[r, "k_1 = 0\cdot9"] & \mathrm{RPN} \arrow[r, "k_3 = 0\cdot9"] & b \arrow[r, "k_5"] & c \arrow[r, "k_7 = 0\cdot9"] & a \arrow[r, "k_8 = 0\cdot9"] & a_3 \arrow[r, "k_9"] & O_2 \\ & A \arrow[u, "k_2"'] & A \arrow[u, "k_4"'] & A \arrow[u, "k_6"'] & & & \end{tikzcd}$$

k_5	k_9	RPN	b	c	a	a_3
0·9	0·10	− 26	− 47	− 30	+ 23	+ 44
0·9	0·07	− 12	− 5	+ 18	+ 85	+ 49
0·9	0·04	− 4	+ 14	+ 33	+ 85	+ 25
0·2	0·5	− 10	+ 17	− 12	+ 12	+ 7

this single assumption, one may make an accurate mathematical model of the complex sequence of reactions. The equations for electron transfer through the eight bimolecular steps are written in a shorthand notation in which each chemical equation consists of the reactions above one another, the velocity constant and reaction products being indicated by following the arrows[2]:

$$O_2 \xrightarrow{k_1} a_3''' \xrightarrow{k_3} a''' \xrightarrow{k_5} c''' \xrightarrow{k_7} c_1''' \xrightarrow{k_9} b''' \xrightarrow{k_{11}} fp \xrightarrow{k_{13}} \mathrm{RPN} \xrightarrow{k_{15}} \mathrm{AcAc}$$

$$O_2 \xleftarrow{k_1} a_3'' \xleftarrow{k_3} a'' \xleftarrow{k_5} c'' \xleftarrow{k_7} c_1'' \xleftarrow{k_9} b'' \xleftarrow{k_{11}} rfp \xleftarrow{k_{13}} \mathrm{RPN} \xleftarrow{k_{.5}} \mathrm{BOH}$$

Additional reactions causing inhibition of the bimolecular processes are represented by the combination of an inhibitory substance (*I*) with one of the reactants, so that the concentration of the reactant available for electron transfer is diminished. Physical argument readily indicates that an inhibitor acting at a single point by combining, for example, with the reduced form of a respiratory component would cause a decrease in the concentration of the oxidized form of those components on the substrate side of the interaction site, and an increase in the concentration of the oxidized form of those components on the oxygen side of the interaction site. Thus when there is only one interaction, the site is invariably identified by a − to + cross-over.

Table 2 gives values for the changes of the steady-state oxidation-level of the cytochrome components in response to a decrease in the velocity constant for interaction with the substance *A*. This simulates the exhaustion of added adenosine diphosphate. In this calculation we have summed the concentrations of the active and inactive forms of the intermediate, since in the chemical system these are apparently spectroscopically indistinguishable[3]. The first row of data simulates conditions for the cytochrome chain where the cross-over point is found between cytochromes *c* and *a*. A decrease in the velocity constant for the oxygen reaction (experimentally caused by the addition of azide[12]) can move, in successive steps, the cross-over point to between components *b* and *c* or between components reduced pyridine nucleotide and *b* as indicated in the second and third rows. These analogue-computer data verify the method which we have used experimentally for showing that three sites of interaction exist in the respiratory chain of mitochondria. In the fourth row the velocity constant between cytochromes *b* and *c* is diminished and a 'reversed cross-over' is obtained. The − to + cross-over points between reduced pyridine nucleotide and *b* and between *c* and *a* are, however, valid indications of interaction sites.

In a five-component system, together with further data not included here on a seven-component system, this analogue computer representation of three sites of interaction affords a basis for restatement of the cross-over theorem in a more useful form than that given previously. We will state the theorems that apply to a system involving flux from a substrate to oxygen through a series of carriers which exist in oxidized and reduced forms. The reduction of components is denoted by − and their oxidation by +. For interactions that cause decreases of flux, we can state: (1) an interaction site lies between a − to + change in the sequence from substrate to oxygen; (2) components between oxygen and the first site will always show + changes, while those between substrate and the last site will always show − changes; (3) a cross-over point near the oxygen end of the chain can be shifted to the next site of interaction by a decrease of activity in the oxidase portion of the chain and vice versa; (4) a + to − change (reversed cross-over) does not identify an interaction site.

These theorems appear to apply to many other types of systems, for which the term 'substrate' can be replaced by the term 'source' (source of flux) and 'oxygen' by 'sink' (a sink for the flux). In this case, 'reduction' (−) implies an accumulation of the source material and 'oxidation' (+) a depletion of the source material. In the case of a semi-conductor, the substrate would be represented by electrons and the oxygen by holes.

The demonstrability of cross-over points for all sites of interaction depends on a number of factors, the most important of which are the intensity of the interactions and their effect upon the flux through the system. Another factor to be considered is the steady-state level; components which are nearly fully oxidized or reduced may show changes that are difficult to measure, since a component that is highly oxidized will be insensitive to an oxidizing interaction and vice versa. In such cases, inhibitors are useful to alter steady-state levels and thus to increase the demonstrability of cross-over points. Inhibitors also shift the cross-over point from site to site along the chain and thereby allow successive demonstrations of the interaction sites of the chain.

Current- and Fluid-flow Models

Holton[10] and, more recently, Lundegårdh[13] have respectively proposed current- and fluid-flow models for the electron transfer system, and the former has made a detailed study of the response of the current-flow model to changes of resistance[10] to determine whether it simulates cross-over behaviour. His corrected results[11] agree with the generalization obtained with the analogue computer and show the movement of the cross-over point (− to + change) with decreases of flux illustrated in Table 3 together with a + to − change also indicated by the last row of Table 3. Such a reversed cross-over does not indicate a site of interaction (see below).

One of us (C.M.C.) has made a complete analysis of a current-flow model containing seven resistors in which R_2, R_4, and R_6 may be increased (see Table 3). It is found that ΔE_1 is always negative and ΔE_5 and ΔE_6 are always positive. We define, in accordance with Table 1, a cross-over point as a − to + change

Table 3. CROSS-OVER BEHAVIOUR OF A CURRENT-FLOW MODEL, ILLUSTRATING THE CONCEIVABLE RESPONSES TO DECREASES OF CURRENT FLOW CAUSED BY INCREASES OF RESISTANCE AT THREE SITES—R_2, R_4, AND R_5

	ΔE_1	ΔE_2	ΔE_3	ΔE_4	ΔE_5	ΔE_6
a	−	−	−	−	| +	+
b	−	−	−	| +	+	+
c	−	−	+	+	+	+
d	−	| +	+	+	+	+
e	−	+	+	−	+	+
f	−	+	−	−	+	+
g	−	+	−	+	+	+
h	−	−	+	−	+	+

proceeding from e_1 to e_6 in response to a decrease of flux or current flow. If one sets down all the conceivable combinations of signs for ΔE_2, ΔE_3, and ΔE_4 an analysis of the circuit shows rows *a*, *b*, *d*, *e*, *f*, and *g* to be realizable with appropriate changes of flux. Thus all three sites of interaction can be readily identified by the − to + cross-over. Rows *c* and *h* appear to identify false sites of inhibition, but the analysis further shows that no combination of resistance changes can possibly produce potential changes leading to rows *c* and *h*. In summary, a − to + change associated with a decrease of flux identifies one of the sites at which interaction has occurred.

Neither the current- nor the fluid-flow model represents the bimolecular interaction of electron transfer in the chemical system. The reaction of soluble cytochrome *c* with the cytochrome *a* component of a solubilized cytochrome is bimolecular:

$$c'' + a''' \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} c''' + a'' \qquad (1)$$

This reaction holds for lower cytochrome *c* concentrations, although the reaction at high cytochrome concentrations is complicated by the fact that this substance is inhibitory[14]. No reversibility of the reaction has been demonstrated, that is, $k_1 >> k_{-1}$. The same rate law holds to a reasonable accuracy[22] for systems in which the carriers are bound to structures which, in the case of the mitochondria, are probably the cristae. The current-flow model (Holton, F. A., personal communication) appears to represent equation 1, but k_{-1} must be equal to k_1, a condition clearly not true for the chemical system. A more general analysis shows that the current-flow system represents, in addition to the reversible system of equal forward and reverse velocity constants, an irreversible system with a rate constant equal to the reciprocal of the sum of all the resistances.

The kinetic response of the current- and fluid-flow models is not representative of equation 1. While Holton makes no claim that the current-flow model represents chemical kinetics, Lundegårdh does so for the fluid-flow model. The chemical equation for the next step in the reaction is:

$$a'' + a_3''' \overset{k_3}{\rightleftharpoons} a_3'' + a''' \qquad (2)$$

From equations 1 and 2, the differential equation for $k_{-1} = 0$ has two product terms:

$$-\frac{da'''}{dt} = k_1 c'' a''' - k_3 a'' a_3''' \qquad (3)$$

As illustrated by this example, and for any mechanism in general, the rates of reactions in a cytochrome system depend on two chemicals, since oxidation-reduction reactions are involved. The systems of Lundegårdh and Holton depend on the analogue of only one chemical, and thus differ in a most fundamental way.

This research has been supported in part by a grant from the National Science Foundation. The assistance of Mr. Michael Barr in obtaining the data for Table 2 is gratefully acknowledged.

WATER RESOURCES AND WATER NEEDS IN SCOTLAND

A SYMPOSIUM on "Water Resources and Water Needs in Scotland" was held by Section E (Geography) of the British Association on September 1. The following papers were read: "The Need for River Flow Studies", by R. Maclagan Gorrie (Royal Scottish Geographical Society); "Measuring River Flow and Estimating Floods", by P. O. Wolf (University of London); "Evaporation and Land Use in Water Conservation Studies", by F. H. W. Green (Nature Conservancy); "Hydro-electric Development in Scotland", by P. L. Aitken (North of Scotland Hydro-electric Board); and "Industry in relation to Water Supply", by L. B. Aitken (Scottish Council Development and Industry).

The abundance of pure water has in the past been a major influence in the siting of Scottish developments such as the early linen and cotton mills, paper making, brewing and distilling. It also fixed the sites for aluminium production, and, more recently, for the North of Scotland Hydro-electric Board's sites in Perthshire, Argyll and Ross. The new atomic power stations and chemical factories make very big demands on water supply, so requests for 5 million gallons a day are now common.

The demand for electricity in Scotland is growing by 7 per cent per annum, so that new power stations have to be planned to meet a doubling of output every ten years. The base load which is maintained over the whole twenty-four hours can best be met by steam or nuclear stations, but the fluctuations above this minimum are a different matter, and can best be met from steam power or by hydro-electric stations. The peak load may be for only a few hours in each day but will cost three times as much as the base load to produce. Hydro-electric stations of the conventional or of the pumped-storage type are best suited to produce the peak load and can do so at less cost.

Scottish river supplies are thus so valuable that every effort must be made to safeguard them, and the use of this basic resource must be planned. The behaviour of rivers can best be judged from stream-gauge records, but the amount of water reaching a stream-bed is an uncertain fraction of the rain which has fallen within its catchment. To get an accurate picture of the value of a river we must therefore have a knowledge of the rainfall, not only in total but also in intensity, and with enough rain-gauges to provide a grid which will show the pattern of local storms.

Stream-gauging has lagged seriously behind other countries; in Scotland it was left to private initiative, the pioneer being Capt. W. N. MacClean, who, at his own expense, undertook gauging from 1912 onwards on the Rivers Garry, Moriston, Ness, Lochy and Dee. The data he recorded are of great value, but unfortunately this was not appreciated when he offered them to various Scottish bodies; these records are now being used by the London School of Economics for the training of hydrologists.

The "Surface Water Year Book", now issued officially, covers from 1945 onwards. The Scottish mainland has forty-two major catchments, out of which rainfall–run-off data are presented for sixteen of them or their tributaries. Unfortunately, in the case of two of our most important rivers, the Tay and the Spey, the rainfall data are considered by the Meteorological Office to be inadequate to present rainfall in detail, and the flow of both is affected by transfers of water between the two across their common watershed for hydro-electric supply. Excluding the Tay and Spey, ten catchments of more than a hundred square miles and seven catchments of less than a hundred square miles are recorded, so that their rainfall–run-off ratios can be determined. The readings for all of them for a number of years give a straight-line graph showing a ratio of run-off (A) to rainfall (R) of $A = 7R/8 - 8$ (in inches). This differs radically from that given for the Thames basin by E. C. Bilham, in which $A = 0{\cdot}57R - 6{\cdot}05$ (in inches). This confirms that their behaviour is radically different, as must be expected considering the greater altitude and heavier rainfall of the Scottish Highlands and the very large area of peat which covers them.

Evaporation (including the transpiration from plants) is the largest single item in accounting for the difference between rainfall and run-off. In assessing this loss, two fundamentals have to be separated, namely, the energy causing the evaporation and the water available for the process. By guarantee that water supply is never a limiting factor, we arrive at a figure of 'potential evaporation' which can be considered as a climatic factor comparable with, say, rainfall or air temperature, but to make valid comparisons there must be more or less arbitrarily defined standard conditions.

A grass sward free of obstructions and conforming to the ordinary requirements for a meteorological reporting station has been used by F. H. W. Green, of the Nature Conservancy staff, in producing valuable contrasts in four Highland readings, as shown in Fig. 1. Kinlochewe is in the maximum rainfall belt, immediately to the west of the main watershed; Prabost in Skye is to the west of this, and Lossiemouth well to the east of it. Achnagoichan in Speyside is intermediate in an intermontane basin but at an elevation of 1,000 ft. As the effect of alternative land uses upon the available water supply is the ultimate objective, steps are now being taken to determine the potential evaporation in the centre of a large homogeneous area of spruce.

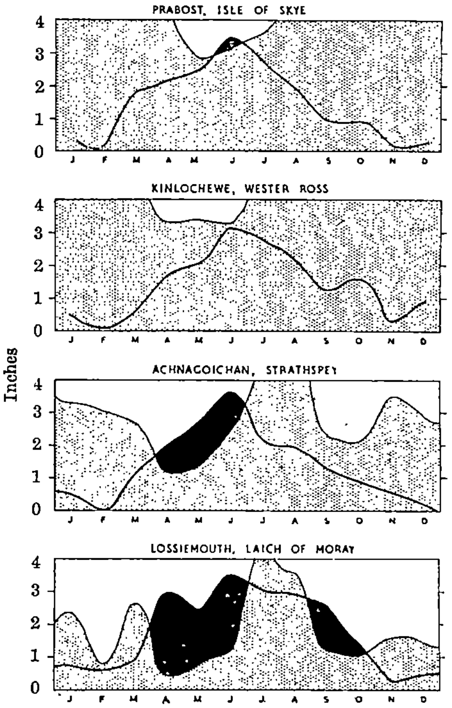

Fig. 1. -——, Rainfall; ——, potential evaporation; ■, excess of potential evaporation over rainfall, all for 1957

A historical analysis of damaging floods so far recorded in Scotland gives the impression that floods and damage occur more frequently at present than they did in the past. When one attempts to analyse this trend in terms of changing land use and run-off conditions, there is already apparent a widespread deterioration in the condition of our moorland peat as a ground cover. This has been brought about by the moor burning, which has increased in many districts as an answer to the coarsening of the grasses following upon the use of sheep only over a long period of years. When robbed of its protective cover by fire, peat behaves in the same way as any other eroding soil; in the first heavy rain after the fire it forms a surface slime which seals off the top, thus preventing normal penetration of the rain through the underlying layers of soil and rock to join the water-table. Instead, it all goes off in surface run-off which, of course, increases the 'flashiness' of flood peaks.

Other changes in land conditions which contribute to damaging flood peaks are the increased bank erosion along many of our highland streams, the use of heavy drainage ploughs on sheep-runs and afforestation areas, and the commercial 'skinning' of peat from the bogs for commercial purposes. Flood intensities are clearly a function of the intensities of rainfall and of the catchment characteristics, including the limits of retention capacity as influenced by land use and misuse. The hydrological estimate of 'maximum possible floods' or 'probable maximum floods' starts, however, with studies of storm maxima, either by transposing the worst recorded storm for the region on to the catchment in question, or by building up from other meteorological data.

Since the Reservoir (Safety Provisions) Act, 1930, has laid the responsibility for checking the safety of dams upon a panel of engineers, the technique advocated in the Institution of Civil Engineers' Interim Report, 1933, is to plot the peak discharges for all the recorded rivers in Britain in cusecs per thousand acres of catchment for the actual catchment area ; the curve thus produced has been of the greatest value as a guide in experienced hands. A revision of this report is now in preparation and will include flood data collected between 1933 and 1957, and this will be a further step in helping the designers of dams and also those wrestling with flood forecasting.

Local authorities are continually trying to attract new industry to their area, but in many cases do not know what their water resource amounts to. Demands of 5 million gallons a day, or even 20 million, are now met with ; but the number of sites which can cater for such demands is limited, and when the few still to be exploited in England are used up, there will remain only the Scottish Highlands. Unfortunately, we do not know the potential of many Scottish rivers and it is imperative that more data and more reliable data should be collected. Guesses are not good enough ; an industrialist will site his factory where he knows there is enough water, and not on another more desirable site where there might be enough.

In the past it has not been the duty of a local authority to measure river flows. It is a highly specialized job and an expensive one if carried out according to the high standards of the Land Drainage Division of the Department of Agriculture for Scotland. The programme of the Division is being greatly extended; but even so, only a fraction of Scottish rivers is now being measured. Under the river purification boards now appointed for eight lowland rivers in Scotland, minimum or nadir flows are being measured, as this is the crucial figure needed to determine permissible pollution. Other county officers, including planners, road engineers and police, want data for safety precautions and flood warning systems, and are adopting various types of gauging less expensive than the Land Drainage Division's specification.

The Royal Scottish Geographical Society has recently established a standing committee for river flow studies and is defraying the expenses of meetings ; the group includes the four university geography departments, civil engineers, land drainage and water use specialists, meteorologists and land use planners. The main tasks are to collate flood records, review any research work and encourage fresh efforts in research and survey of river behaviour, and ensure publication of suitable material ; to advise local authorities when called upon ; and where warranted, to agitate for action on flood control ; to arrange the formation of 'flying squads' for immediate reconnaissance of floods as they occur ; and to encourage longer-term studies bearing upon evapo-transpiration and the ultimate demands on existing water supplies. So far, the committee's main function has been to provide a platform for discussion ; the organization is a very long way behind its Danish counterpart, the Hydrology Section of the Danish Heath Society at Slagelse. Hitherto, efforts to get funds have failed and the programme is crippled because of this.

The measurement of the flow of water, starting with surface run-off and finishing in the sea, can properly be considered the sphere of geographers skilled in hydrometry ; the basic knowledge must needs include the ecology and geology of the catchment as well as the engineering of a gauging site, the best equipment for the given conditions, and the drill for using the instruments properly. Too much of current press writings about floods and water resources shows a superficial approach. It is hoped that this may be counteracted to some extent by getting an increasing number of geographers using a scientific approach and in close collaboration with the engineers to undertake hydrometric work as well as climatological stations, and so build up a fuller knowledge of the nation's water resource.

R. Maclagan Gorrie

NUCLEAR POWER STATIONS

WORLD PLANS AND EXPERIENCE

At the first Geneva Conference on the Peaceful Uses of Atomic Energy in 1955 only the U.S.S.R. could claim to have a nuclear power station in operation, and that on little more than an experimental scale. Producing 6,000 kW., it was generally considered, from the description provided, to be no more than a demonstration of feasibility. The building of Calder Hall was well advanced, but it was not in operation and its economy and reliability were still to be demonstrated. The United States, with ample and cheap supplies of fossil fuels, felt less urgency for the development of nuclear power stations and greater difficulty in achieving economic parity with conventional stations at home.

The three years between the first and second Conferences at Geneva have seen very great advances in this field in many countries. The feasibility of nuclear power stations is no longer in question and discussion now centres on the type of reactor to be used, the date by which it will provide electricity as cheaply as conventional stations, in particular national economies, and the rate at which nuclear power stations can be built. In 1955, only the United Kingdom had a national nuclear power programme, and it is significant of the rate of advancement in this period that within two years this programme had been substantially increased, based on the development potential revealed by the design of the first stations. At the second Conference recently concluded, a number of countries presented papers setting out their plans for the construction of nuclear power stations, not as vague and distant hopes, but covering generally the next decade and based on careful assessments of demands for electricity, supplies and costs of fossil fuel, the economics of reactor systems and the availability of finance and technological man-power.

Between those countries where fossil fuel or hydro reserves are at present adequate, such as the United States and Sweden, and those which urgently require a new source of energy, such as Japan and Italy, there are a number of differences which have led to two main approaches. The former group tend to have wide ranging programmes of prototype demonstration reactors, whereas the latter concentrate on systems already developed in other countries. Western Europe, through the agency of Euratom, may be in a special position, combining concentration by individual countries with diversity over the whole Euratom area.

Running through most of the papers presenting national programmes is the determination to achieve ultimate independence, at least in the design and construction of the stations, although several countries will clearly have to rely on imports of uranium and thorium for fuel. At the same time, there is recognition of the heavy demands on scientific and technological man-power, as well as on industrial capacity, which the development of a reactor system to a commercial scale makes, and the realization that in the early stages there must be some degree of dependence on other countries.

For those countries which have accepted the need to import their first nuclear power stations, the choice virtually rests between two systems: the graphite-moderated, gas-cooled reactor developed from Calder Hall, and the water-cooled and moderated systems, in the form of the pressurized water reactor at Shippingport and the boiling-water reactor nearing completion at Dresden in the United States.

No very clear picture as to the relative merits of cost of power in these two types of station emerged. The gas-cooled reactor has high capital cost, which may be reduced if it is built for the large outputs of which it is capable, and low fuel costs. The boiling-water reactor, particularly, appears to have low capital costs but these are associated with higher fuel charges. Thus, an economic comparison is very dependent upon the size of station to be built and the rate of interest chargeable to the capital investment. The fact that the former uses natural uranium, thereby eliminating the need for a diffusion plant or the importation of enriched fuel, offers the prospect of earlier national independence.

Although the number of power reactor systems already built and operating is limited, the range will clearly be extended in the near future, with the United States and the U.S.S.R. leading the way in diversity. The United States, having adequate conventional fuel resources, has been concerned chiefly with the development of reactors for submarine propulsion, and in the field of electricity generation has encouraged the construction of power demonstration reactors, of relatively small output, primarily with a view to export. The availability of comparatively cheap enriched uranium has been invaluable in permitting the study of small reactors of various types, but it is noteworthy that the U.S. Atomic Energy Commission has also turned its attention recently to the gas-cooled, graphite-moderated system.

The United Kingdom, while pursuing its policy of concentrating its main effort on developments of Calder Hall to provide large units for the home market and introducing modifications such as ceramic fuel and beryllium cans to permit higher operating temperatures and consequent greater efficiency, is considering alternatives such as the replacement of graphite by heavy water as the moderator. That such alternatives must satisfy the criterion of offering economic advantages over developments of the Calder Hall type is clear from the announcement of the abandonment of work on the sodium-cooled graphite-moderated system, which was adjudged to offer no economic inducement. Both the United Kingdom and the United States are devoting considerable effort to the longer-term project of a fast fission reactor, and the advantage of the positive breeding gain which this system permits has been widely recognized. Thus, the Japanese paper speaks of relying on foreign thermal reactors for the early stages of the programme, while concentrating Japan's own research and development effort on the design of breeder reactors to be available commercially about 1970.

Reviewing typical national programmes, it is interesting first to compare the countries in which the need for nuclear power is most urgent. The plan to provide 5,000–6,000 MW. of installed capacity in the United Kingdom by 1966 is well known. In Italy, five organizations are each planning to build a station, the combined electrical output being 900 MW., but no precise time-scale is set. The Japanese paper gives detailed economic analyses, both of the cost of stations and the relation of expenditure to the estimated national income. Besides setting targets of 600 MW. by 1965 and 7,000 MW. by 1975, it forecasts that the proportion of equipment manufactured in Japan would rise from 60 per cent in the period 1962–65 to 93 per cent after 1967. The Netherlands, with a present import of about half its fuel supplies and an increasing demand, proposes to have 3,000 MW. of nuclear power station capacity installed by 1975, sufficient to supply 50 per cent of the electrical output. The first step towards this aim is a 100-MW. station in operation by 1962.

France normally imports about 40 per cent of the energy it consumes, the security of which must be dependent on adequate trade balances and also on satisfactory political conditions. The discovery of uranium ores in metropolitan France led to a power programme similar to, but smaller than, the British, in which the most economic system was sought. The early stations, which employ natural uranium and are moderated by graphite and cooled by carbon dioxide, have been designed as prototypes, each differing somewhat from the next (both horizontal and vertical fuel channels have been tried and pressure vessels have been constructed both of prestressed concrete and of steel). The present programme is for two civil power stations to be completed by the middle of 1961 totalling 233 MW. This series of reactors is then to be continued by putting into operation every eighteen months an additional plant, more powerful and more efficient than the preceding one.

Western Germany, with no urgent need to supplement conventional sources of power and a tradition of scientific and industrial ability, plans to investigate a range of reactor systems, including some of its own design, and expects by 1965 to have in operation four or five 'demonstration' stations each producing about 100 MW. of electricity. These stations will be built for utility companies and not for the Government, though it is proposed that one-third of the capital shall come from public funds. With several research reactors from the United States and the United Kingdom, and bilateral agreements with Canada and the United States for the supply of uranium concentrates and enriched uranium respectively, Western Germany is making great efforts to overcome the handicap of a late start in the field of atomic energy.

At the other end of the scale, both the U.S.S.R. and Poland state that their fossil fuel deposits are adequate and they have no present need for nuclear power, though the Soviet Union makes the exception that it would be useful in certain remote areas. Although they had not reported any new stations since the one they described in 1955, the Russians announced during the Conference the construction of a station in Siberia with an ultimate output of 600 MW.(e). The information given suggests that it is a dual-purpose station with electricity as a by-product. They also showed in the scientific exhibition at the Conference a design for a 150-MW. station using gas-cooled, heavy water-moderated reactors. The Polish programme is based on the conclusion that nuclear stations will be more economic than conventional stations within twenty years, and it is therefore planned to install 800 MW. capacity between 1965 and 1970, with a further 1,000 MW. capacity added in the following five years. It is hoped that the reactors in these later stations may be of the fast breeder type.

An interesting variation is provided by Sweden, where the hydro-electric capacity is adequate to meet demands for the next fifteen years, but where there is virtually no domestic conventional fuel. This lack of coal and oil, combined with the long winter, has caused the Swedish programme to be directed towards the use of nuclear energy for district heating, with the production of electricity by back-pressure turbines as a by-product. By 1965 it is intended to build six reactors to supply heat and only one 100-MW. electrical power station. As the available hydro resources are fully utilized, an expansion in the nuclear power station programme is envisaged, providing a total installed capacity of about 2,000 MW. by 1975.

Other countries, including India, Spain and Roumania, presented papers forecasting the construction of nuclear power stations within the next few years.

The range of experience in operating power-producing reactors is at present both limited and unrepresentative, being based largely on units planned primarily for military purposes or on small-scale demonstration reactors. The 80 per cent availability reported for the Calder Hall reactors is gratifying proof of reliability, but the extremely low incidence of defective fuel elements achieved is not conclusive evidence of performance of the power station because of the relatively low level of irradiation imposed by the military requirements. In the same way, the remarkable performance of the submarine reactors cannot be taken as a reliable guide to the behaviour of a similar type of reactor designed to standards which permit the economic generation of electricity. Thus, both the running costs of the present type of power reactors and their span of useful life, which have an important bearing on the assessment of their economics, can only be finally established when a significant proportion of their estimated life of fifteen or twenty years has been achieved.

Nevertheless, there was at the Conference a high degree of confidence in all the countries concerned that these factors would prove to be favourable to the economic generation of power.

UTILIZATION OF INORGANIC NITROGEN SOURCES BY PLANTS

ONE session of Section K (Botany) of the British Association meeting at Glasgow, held on August 29, was devoted to a consideration of the problems involved in the utilization of inorganic nitrogen sources for amino-acid and protein synthesis by plants. Emphasis was primarily upon the nitrogen fixation process, although recent progress in the use of combined inorganic nitrogen sources was also reviewed.

Dr. G. Bond (Glasgow) stressed that nitrogen fixation constitutes one of the few fundamental processes of the living world and serves to maintain the supply of combined nitrogen in soils and oceans. Without fixation the opposing actions of the denitrifying bacteria would probably reduce the nitrogen status of natural soils to levels incapable of supporting most forms of plant life.

What, then, are the organisms capable of effecting nitrogen fixation ? During a critical review of recent evidence gained largely by the use of the heavy isotope of nitrogen (nitrogen-15), Dr. Bond concluded that no faculty for fixation resides in members of the Angiosperms, Gymnosperms, Pteridophytes or Bryophytes except where there is symbiosis with certain lower organisms. Some blue-green algae (*Nostoc*, *Anabaena* and *Cylindrospermum*) have long been recognized as efficient nitrogen fixers. Certain other members of the Cyanophyceae are incapable of fixing nitrogen, as are all green algae so far tested. The position of the fungi is less certain, and much confirmatory work would seem desirable. While the nitrogen nutrition of most fungi would undoubtedly seem to be based on combined nitrogen, there is preliminary evidence that certain fungi (soil yeasts assigned to the genera *Saccharomyces* and *Rhodotorula*) have some capacity for fixing nitrogen.

The main free-living nitrogen-fixing organisms are without doubt to be found among the bacteria. The genera *Azotobacter* and *Clostridium* include species with an almost world-wide distribution that can effect nitrogen fixation. However, it remains uncertain whether they are sufficiently abundant in soils to permit of extensive nitrogen fixation. Other species for which there is evidence of ability to fix nitrogen include *Azotomonas*, *Aerobacter*, *Desulphovibrio*, *Methanobacterium* and *Pseudomonas* ; positive results have also been obtained for photosynthetic bacteria, including *Rhodospirillum*, *Chromatium* and *Chlorobium*, and so these species match the Cyanophyceae in metabolic powers.

In many plant habitats symbiotic nitrogen fixation is probably much more important than any of the above types of asymbiosis. Nitrogen fixation by legumes, the root nodules of which contain *Rhizobium* as the endophyte, has been a basic agricultural practice and is still of great importance in certain less industrialized countries. In areas of natural vegetation other Angiosperms capable of forming root nodules may be more important than the legumes. Eight genera so far seem important: these are *Hippophae, Elaeagnus, Shepherdia, Myrica, Casuarina, Coriaria, Alnus* and *Ceanthus*. Undoubtedly the fixation is due to the presence of symbiotic micro-organisms within the nodules, but the nature of these remains uncertain. The importance of certain of these species in the maintenance of nitrogen fertility may well have been greater in earlier times. Alder and bog-myrtle were very prevalent in Britain in pre-agricultural times and they may then have been the principal nitrogen fixers. Recent direct evidence indicates that in Alaska alder figures regularly in plant succession on recently de-glaciated lands and has served to increase soil nitrogen markedly. Sea-buckthorn (*Hippophae*) was another plant that rapidly established itself after the ice-age in Scandinavia and possibly in Britain; this may have been due in part to its possession of nitrogen-fixing nodules.

A number of Gymnosperms, particularly members of the family Podocarpaceae, bear large numbers of nodular structures on their roots. Although reports exist that nodulated plants of *Podocarpus* can continue to grow actively without a combined nitrogen supply, studies with nitrogen-15 have failed to confirm the ability of the plant to fix nitrogen. Various members of the Cycadaceae also produce nodulated roots resembling those of alder. These nodules appear to contain an alga identified as a *Nostoc* or *Anabaena* species, and when detached nodules of *Ceratozamia* and *Encephalartos* were exposed to elementary nitrogen-15, clear evidence of strong nitrogen fixation was obtained. The earlier dominance shown by the cycads in many parts of the world may have been associated with their ability to utilize elementary nitrogen at a time when the combined nitrogen status of most soils was comparatively low.

Several other intriguing possibilities for symbiotic nitrogen fixation exist. The nitrogen-fixing bacterium, *Beijerinckia*, has been isolated from the leaf surfaces of several Indonesian plants and may make symbiotic nitrogen fixation possible. The 'leaf-nodules' (cavities in the leaf surfaces containing dense growth of bacteria) of *Pavetta, Psychotria* and *Chromelia* have been assigned nitrogen-fixing ability. Cavities containing nitrogen-fixing blue-green algae are also known; thus, the water-fern *Azolla* is associated with *Anabaena*, while certain liverworts, including *Blasia*, accommodate *Nostoc*. Finally, the lichens seem to provide other examples of symbiotic nitrogen fixation. About 8 per cent of all lichen species contain an algal symbiont of the blue-green type, and recent experiments using nitrogen-15 have provided definite evidence of nitrogen fixation in three such species (*Peltigera, Collema* and *Leptogium*). No ability to fix nitrogen resided in lichens containing a green-algal symbiont.

The other papers of the session were concerned with the physiology and biochemistry of nitrogen utilization. Irrespective of whether inorganic nitrogen-15 is supplied as elementary nitrogen, nitrate or ammonia nitrogen, the sequence in which the nitrogen-15 atoms enter organic nitrogen compounds is closely similar for most plants. This suggests that all forms of inorganic nitrogen are converted to a common intermediate before being incorporated into organic compounds. The bulk of the present evidence indicates that this intermediate nitrogen compound is ammonia. Earlier claims that hydroxylamine occupied this key position in the nitrogen fixation process seem to have been discounted.

Dr. G. Leaf (Glasgow) reviewed the older evidence showing that during the fixation of elementary nitrogen-15 by *Azotobacter, Clostridium* and soya-bean nodules, the nitrogen-15 probably first entered ammonia and then glutamic acid and the amides, asparagine and glutamine. Similar studies have been carried out in the Glasgow laboratories using nodules from the roots of alder. The pattern of distribution of nitrogen-15 atoms between various nitrogenous compounds differed significantly from that obtained with the legumes. It is noteworthy that citrulline, an amino-acid otherwise rarely encountered, is a major component of these root nodules, and was labelled with nitrogen-15 nearly as heavily as glutamate. Indeed, the labelling of the carbamyl-nitrogen atom (citrulline contains three nitrogen atoms) was substantially heavier than that of the α-amino-nitrogen of the glutamate. This quantitative difference does not, of course, mean that the primary reactions of nitrogen fixation are different in alder, since an established biochemical pathway shows that the carbamyl-nitrogen of citrulline is derived from ammonia via carbamyl phosphate. It is these early reactions and intermediates of the nitrogen fixation process that are still shrouded with mystery. A great deal of speculation exists concerning their nature and many experimental studies have been made to test the validity of the theories propounded, but as yet no unequivocable conclusions have been reached.

A synthesis of various schemes previously published was presented by Dr. Leaf (Fig. 1).

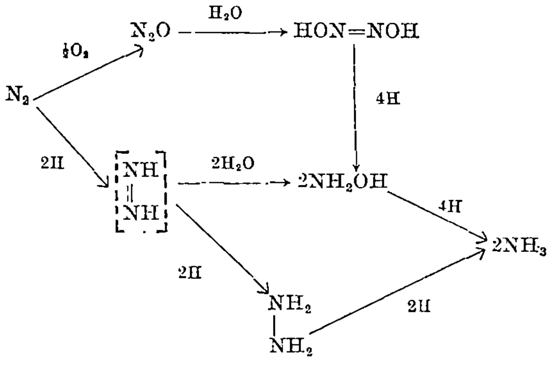

Fig. 1

Uncertainty is encountered in the very first step, which can be represented as involving either an oxidation or reduction. Crucial evidence in favour of either mechanism is still awaited. The problem of the intermediates has been approached by testing whether nitrogen-fixing organisms can utilize them, often after they have been labelled with nitrogen-15. The first intermediate of the reduction pathway postulated is not known to exist in a free form and so cannot be detected. Some support is gained for nitrous oxide as an intermediate since it acts as a competitive inhibitor of nitrogen fixation; but since it can only be utilized by *Azotobacter* at a fraction of the rate of elementary nitrogen, more conclusive evidence would seem desirable. Difficulties arise when later intermediates are tested, for they are often both unstable and toxic to the organism. However, evidence is accumulating to support the intermediary role of hydroxylamine. Hydrazine can also be utilized by *Azotobacter* but, in striking contrast to the assimilatory pathway recognized for elementary nitrogen fixation, the hydrazine-nitrogen was apparently not assimilated into glutamic acid. It is then conceivable that hydrazine is assimilated by processes having no direct connexion with those involved in nitrogen fixation. Thus, it seems probable that the precise details of the chemical pathway of nitrogen fixation will remain unsolved until appropriate conditions are found that enable active fixation to occur in cell-free extracts.

Dr. L. Fowden (London) discussed the assimilatory processes involved in the use of combined inorganic nitrogen sources by plants. The reduction pathway by which nitrate-nitrogen is converted to ammonia seems at last to have crystallized in the following form:

$$HNO_3 \rightarrow HNO_2 \rightarrow HON{=}NOH \rightarrow H_2NOH \rightarrow NH_3$$

Definite evidence is now available from Dr. Nicholas's laboratories demonstrating the existence in fungi (*Neurospora* and *Aspergillus*) of separate enzymes responsible for the catalysis of each reductive step. Naturally, one wishes to see these or similar enzymes established for higher plants. The enzymes, in showing a dependence for various metals, flavin-adeninedinucleotide and reduced phosphopyridine-nucleotides, provide a nice illustration of the importance of trace elements and vitamins in an integrated reaction sequence characteristic of plants.

In higher plants the final reduction product, ammonia, enters organic compounds by being channelled primarily into glutamic acid by reductive amination of α-ketoglutarate or into the amides glutamine and asparagine. Although suggestions are periodically made that alanine and aspartic acid may arise by similar reductive aminations of pyruvate and oxaloacetate, respectively, satisfactory confirmation of these reactions is still required for higher plant systems. Certain mutants of micro-organisms lack glutamic dehydrogenase, and here reductive amination of pyruvate seems to have been established as a major alternative pathway for ammonia assimilation.

Reactions involved in the formation of citrulline and arginine provide secondary pathways for the direct utilization of ammonia. The majority of the other amino-acids required for protein synthesis must gain their nitrogen in a less direct manner. Transamination normally provides the present-day panacea for the problems of their biosynthesis. For this to be effective, it is necessary that all the corresponding keto-acids exist in plants. However, at present only a fraction of the twenty or so acids required have been detected; it remains possible that the others exist at concentrations that are below the present limits of detection but sufficiently high to enable transamination reactions to provide amino-acids at a rate commensurate with protein synthesis.

In some ways the study of protein synthesis in higher plants is more difficult than in micro-organisms and animal tissues. Plant cells tend to store greater quantities of free amino-acids than the other types of tissue and at present it is impossible to gain a reliable insight into the distribution of particular amino-acids within the different phases of a cell. It would seem probable that in mature cells large proportions of certain amino-acids are deposited in the vacuoles and play no immediate part in protein synthesis. This conclusion receives support in that the relative concentrations of various acids in the free amino-acid pool as measured by extraction bear no similarity to the amounts in which they are required in proteins. Preliminary evidence does, however, suggest that amino-acid activating enzymes similar to those present in animal and microbial systems exist in higher plants and may catalyse the first step in the synthesis of proteins by the proposed and now familiar ribonucleic acid - template pathway.

A brief discussion followed the three formal papers. The participation of more complex organic intermediates in the nitrogen fixation process was considered and dismissed as unlikely. Various alternative concepts of the template mechanism for protein synthesis were also aired. L. Fowden

UNIVERSITY DEVELOPMENT IN BRITAIN

By Sir ERIC ASHBY

President and Vice-Chancellor, The Queen's University of Belfast

Under the title "University Development, 1952–1957"[1], the University Grants Committee has published a masterly survey of the British universities over the past quinquennium. It is a book of ninety-two pages. Its importance lies not only in the facts which it records but also in its wise and challenging comments.

On the second page is the most significant fact of all: a list of the members of the Committee. Thirteen out of the twenty names are of men and women who are, or have been, university professors or heads of colleges in universities. The controllers of university finance are at one with the controlled; and upon this simple fact undoubtedly rests the great confidence which universities and the Treasury have in one another. Membership of the Committee must be a strenuous responsibility: over the past quinquennium the Committee met fifty-one times and its sub-committees forty times, and its members spent 107 days visiting 103 institutions. It is a notable record of public service.

The factual part of the book summarizes the growth of universities since 1938–39: an increase in student numbers from about 50,000 in 1938 to about 90,000 in 1956; and in academic staff from about 4,000 to more than 10,000. The average salary paid to academics has about doubled over that period (it was £612 in 1938 and £1,323 in 1956) and the recurrent grant has risen from about £2 million in 1938 to more than £28 million in 1956. In 1938 Parliamentary grants constituted about 35 per cent of the recurrent income of the universities; in 1956 the percentage was more than 70. That such a revolution is being accomplished with so little damage to the integrity of British universities is testimony both to their stability and to the wisdom of successive governments in financing them.

The report records the changes in balance of students entering different faculties over the quinquennium. Arts (which includes law and economics) still has substantially the highest proportion of new entrants (47 per cent in 1953 and 45·6 per cent in 1956). The combined percentage of students entering faculties of science and technology rose from 34·7 in 1953 to 38·7 in 1956. The percentage entering medicine and dentistry fell from 14·6 to 12·6. These figures are reassuring, for they indicate that there is no immediate need to fear that the impact of technology on universities is going to be so violent as to imperil the vitality of more traditional studies. Indeed, there are passages in the report which suggest that the chief danger facing arts faculties may come from within themselves. They may be endangered not by a lack of recruits from the schools nor by competition from other faculties, but (of course, only in some departments in some universities) by an aridity of approach and a poverty of imagination ; a lack of fire in the belly.

It is, perhaps, a philistine approach, but nevertheless one not without its merits, to assess the efficiency of a university system by the percentage of students who emerge from universities with degrees. Compared with American or Australian universities, the record in Britain is good. The report gives some interesting data on this matter, ending with the conclusion that, from a sample of 15,256 students whose records were followed by the Committee, 16·7 per cent left without degrees. This percentage is divided into 11·3 per cent who left through academic failure and 5·4 per cent who left for reasons other than academic failure : a 'wastage' of the same order of magnitude as that reported from the Soviet Union.

One of the features of which Britain can be proud is the way in which State scholarships and local authority awards have brought the universities within reach of almost every young man or woman who is talented and who completes a grammar school education. Three out of every four students at British universities are receiving financial assistance. The proportion varies in different parts of the country : it is highest in Wales, low in Scotland (but this is partly offset by the greater numbers of students per thousand of population in Scotland) and lowest in Northern Ireland (where the sole reason is the parsimony of local authorities). But, as the report points out, the very liberality of local authorities in England causes its problems. Local authorities (quite rightly) allow students to hold awards in any university. This has two consequences : it 'creams off' the best students into a comparatively small number of universities, and so perpetuates inequalities in the intellectual standards of students among universities ; and it increases the pressure on student accommodation, for many students take advantage of this invitation to mobility by attending universities in other parts of the country in preference to universities near their own homes. The Committee sees no remedy to the first of these consequences and it welcomes the second consequence ; though it adds the rider that if more and more students are to leave home to attend universities, the universities for their part must take more trouble than some of them are taking to provide sympathetic supervision, especially during the first year.

The chapter on scientific research in universities has some interesting figures on the amount of research in universities which is sponsored by outside bodies. In the United States a dangerously high percentage of the income of a university may come from this source (one typical private university in the Middle West gets 22 per cent of its recurrent income from outside for sponsored research). The Committee's figures are reassuring : they indicate that only 6·5 per cent of the income of British universities is from this source, and half of that is from the research councils and Government departments, which in general put no restriction on the nature of the research or on its publication. Recently, the Department of Scientific and Industrial Research has taken a much more prominent part than heretofore in giving money both for research projects and for postgraduate awards ; and the Committee very carefully defines its function *vis-à-vis* the Department and the Medical and Agricultural Research Councils over the support of research in universities. The Committee ends by throwing out a challenge which some university departments may be reluctant to accept : a challenge urging universities to regard more favourably than they do at present the possibility of allowing students to work for higher degrees in research establishments off the campus and not administratively under university control.

The chapter on educational problems is convincing evidence (if any were needed) that the Committee is not only a machine for dispensing Parliamentary grants ; it is also a permanent seminar for reflexion on the problems of higher education. Earnest reformers, who would like to see commissions inquiring into university problems in Britain, would do well to ponder this chapter ; for it may well lead them to the conclusion that the sort of inquiries which ought to be made are, in fact, already being made, by a body of people who command the respect of the academic world and the confidence of the Treasury. What does the Committee regard as educational problems ? The pressure (often from professors who have not the intellectual courage to know what to omit from their teaching) to extend courses beyond the common 3-4 years ; the overcrowding of the syllabus (often on the ridiculous assumption that after leaving the university the graduate will never again learn anything new) ; the need to ensure that a graduate has a 'cutting edge' to his mind ; the very controversial question of special entrance requirements and the influence they have on general education ; the problem of teaching arts subjects in an imaginative way with due regard to exactitude and critical alertness ; the unpalatable fact that even a mediocre scientist or technologist acquires a vocational skill, whereas an arts graduate who is not going to use his subject vocationally needs to be more than mediocre—to make his education worth while the arts graduate must acquire from it not just facts (which may suffice for the mediocre scientist or technologist) but genuine mental power.

So one could go on. No virtue, no weakness, no pocket of complacency in British universities escapes the eye of the Committee. To the problems which confront universities in the coming quinquennium the Committee brings wise advice, sympathetic and tactful criticism, and lucid reasoning.

OBITUARIES

Dr. N. Miller

NICHOLAS MILLER was born in Liverpool on July 4, 1916, and died suddenly at his home in Edinburgh on May 4. Into this short span was crowded a range of experiences and the growth of a reputation that any man might envy. Such was the universality of his talents that, although a classicist at school, he entered the Imperial College of Science and Technology as an entrance scholar in chemistry and had a brilliant undergraduate career culminating in a first-class degree in 1937. After two years research in physical inorganic chemistry he obtained his Ph.D. and a Commonwealth Fund Fellowship. Characteristically, Miller decided on a change not only of scene but also of academic experience, and for two years worked in oil geology and technology in the University of California. In 1941 he joined the Suffield staff of the Canadian Department of National Defence, where his numerous qualities were speedily recognized, and a few years later he was appointed to the National Research Council staff at Montreal participating in the Anglo-Canadian Atomic Energy Project.

In July 1946 Miller was transferred to Chalk River and began those distinguished investigations on the radiation-induced oxidation of ferrous sulphate with which his name will always be especially associated. In 1947 he went as an I.C.I. Fellow to the Department of Natural Philosophy at Edinburgh and in 1949 was made senior lecturer in radiochemistry. During the past ten years he has led a small, but exceptionally effective, group of radiation chemists, and from his pen there came a succession of definitive papers dealing mainly with chemical dosimetry, or more latterly, with the dependence of radical and molecular yields on linear energy transfer. The hallmark of all Miller's work was ingenious, skilfully executed and imaginatively interpreted experimentation described in pellucid prose. His advice was consequently in much demand by national and international bodies, and Miller never shirked the extra work which these duties involved.

Those who knew Miller personally will remember his modesty and integrity, his immense capacity for friendship and his remarkably infectious and tolerant grin which accompanied many a shrewd scientific comment. It is small wonder that some of his English friends have decided to perpetuate his name in annual conferences on radiation chemistry, and that the predominantly North American membership of the sixth annual meeting on Radiation Chemistry of the Gordon Research Conferences should have adopted the following memorial resolution on August 4, 1958:

"Our meeting this year is sadly marked by the untimely death of Dr. Nicholas Miller, late senior lecturer in natural philosophy at the University of Edinburgh.

"Dr. Miller was known affectionately and admired personally and scientifically by the many friends he made in the United States in the course of his repeated travel in this country in the last several years. He participated significantly in current research in radiation chemistry. Through the keenness of his criticism, the precision of his work and the breadth of his experimental and theoretical approach, he made great and lasting contributions to the maturation of the field. The warmth and generosity of his personality and the breadth of his interests outside his work proved a continual inspiration and joy to his colleagues and friends. His death is a loss to radiation chemistry, to science, and to those who had the good fortune to be influenced by him and his work."

F. S. DAINTON

Prof. K. V. Giri

KRAMADHATI VENKATA GIRI was born in 1907 and died suddenly on July 17 at Madras. Since 1950 he had been head of the Department of Biochemistry at the Indian Institute of Science, Bangalore.

Prof. Giri's output of original research extended over a period of more than twenty-five years and covered a wide range of biochemical topics. Phosphatases, especially of leaves, together with free and bound seed enzymes, were early subjects of study. In 1936, interesting observations were made on the amylase system of rice grain during ripening and germination.

Giri made contributions to the analytical chemistry of ascorbic acid and studied its stability under varying environmental conditions. In the early post-war years, vitamin B_1 in ground nut (*Arachis hypogea*) was found to be partly free and partly combined, and a series of studies appeared on the nutritive and vitamin value of this important crop. Giri published a long series of papers dealing with blood and nutrition, in which the results of research carried out in other countries were interpreted and applied to Indian conditions. Many of these papers added important new facts. In the field of the biochemistry of blood and tissues, Giri and his colleagues carried out much work on prothrombin and on nicotinic acid. More recently, radial or 'circular' paper chromatography was applied with considerable success to a variety of separations involving amino-acids, peptides, organic acids and vitamin preparations. For example, free *allo*hydroxy-L-proline was obtained from the leaves of sandal (*Santalum album*); the compound had not previously been obtained from a natural product. Agar electrophoresis was successfully applied to the study of serum of proteins. It was found that in smallpox there was an increase in all the globulin fractions and a decrease in the albumin moiety.

Prof. Giri felt the need to spread biochemical knowledge more widely and made a hobby of devising scientific films. He wanted every medical practitioner in India to have access to clinical biochemical services, and this objective was stressed through his films, writings, radio talks and lectures.

Giri was much liked and his untimely death is a loss to Indian science. He leaves a wife and four children.

R. A. MORTON
H. R. CAMA

Dr. Marie C. Stopes

MARIE CARMICHAEL STOPES, who died on October 2 aged seventy-eight, graduated at University College, London, at the time when Prof. F. W. Oliver, Quain professor of botany, was making notable contributions in the field of palæobotany. As a subject for research, she selected the ovule of the living cycads, and this took her to Prof. Goebel's institute in

Munich. The contemporary work on the Palæozoic ovules by Oliver and his associates had made the elucidation of the structure of cycadean ovules, to which the fossils were superficially compared, a real necessity. Dr. Stopes found evidence in the cycad ovules that the integument is a double structure, and simultaneously with the tentative view expressed by Oliver and Scott, concluded that it is the morphological equivalent of the inner integument and free cupular structure of the *Lagenostoma* ovule: an interpretation fundamental to our understanding of the evolution of integumentary structures.

In 1904 Dr. Stopes was appointed to the staff of the University of Manchester. Among many contributions published during the ten years she spent at Manchester was a treatise jointly with Prof. D. M. S. Watson on the distribution and origin of coal balls. Similar concretions from the Lower Cretaceous of Japan, in which country she spent some time during 1907–9, revealed an extensive flora, and several papers describing this were published, some in collaboration with Japanese botanists.

Her interest in the Cretaceous floras was to become more apparent, for at about this time she was asked to work on the collection of Cretaceous plants housed in the British Museum. The two volumes published as the "Catalogue of the Cretaceous Flora" (1913, 1915) will surely be her best-known scientific work. Preparation for this work took her to many countries. In 1911 she travelled in Canada and the United States, and in between her Cretaceous studies, discovered what were probably the very first coal balls to be found in America, and made collections from the Carboniferous 'fern ledges' of New Brunswick.

Meanwhile, Dr. Stopes had written a small textbook on palæobotany entitled "Ancient Plants" (Blackie, 1910). It was written particularly for elementary students, and was the first English textbook to bring this rapidly advancing subject before students at a non-specialist level.

She returned to University College in 1914 as a Fellow and lecturer in palæobotany. Several papers on Cretaceous plants followed the publication of the British Museum Catalogue, but throughout the succeeding years her interest became more and more centred on coal, quite apart from the plants that went into its making. Spurred, no doubt, by the effects of war, her palæobotanical knowledge was employed in the service of fuel technology. This proved a very fruitful union, and several memoirs, mostly in collaboration with Prof. R. V. Wheeler, are of fundamental importance in this field of work. Their joint "Monograph on the Constitution of Coal" (Department of Scientific and Industrial Research, 1918) set the stage for all subsequent research on this subject. The new terms (clarain, durain, vitrain, etc.) which she introduced later to the petrology of banded bituminous coal found ready acceptance, and her "Classification of Coal Ingredients" (1935) has been almost universally adopted.

Dr. Stopes founded a small museum on Portland Island, and it was one of her ambitions to make it the possessor of the largest collection of Cycadeoidea in England.

D. W. BRETT

NEWS and VIEWS

Australian University Grants Committee: Sir Leslie Martin, C.B.E., F.R.S.

In 1956, a committee, appointed by the Prime Minister of Australia, Mr. Menzies, to inquire into such matters as "the role of the university in the Australian community; the extension and coordination of university facilities; technical education at university level; and the financial needs of universities and appropriate means of providing for these needs", was set up. The committee was under the chairmanship of Sir Keith Murray, and its report was published in 1957 (see *Nature*, 181, 300; 1958). The report stated that university development in Australia could no longer be left to individual institutions or confined within the boundaries of one State, and the establishment of a permanent Australian University Grants Committee was strongly urged. This has been accepted by the Australian Federal Government, and Sir Leslie Martin has been appointed the first chairman. Sir Leslie is professor of physics in the University of Melbourne, and, since 1948, has been defence scientific adviser and chairman of the Defence Research and Development Policy Committee. He is an Australian by birth, and was educated at Melbourne High School, the University of Melbourne and Trinity College, Cambridge.

Industrial Biochemistry at Manchester: Prof. T. K. Walker

The retirement of Prof. Thomas Kennedy Walker from the chair of biochemistry in the Faculty of Technology at the Manchester College of Science and Technology brings to a close a long and active career in the service of the College. Although Prof. Walker's earliest publications concerned more particularly the field of organic chemistry, his attention soon turned towards chemical changes effected by various bacteria and moulds with particular reference to those of interest to the brewing and fermentation industries. This is reflected in the prominent position occupied by such topics in a series of almost two hundred publications which appeared in conjunction with various collaborators over a period from the late 1920's to the present day. The importance of his work in this field received recognition in 1956 with his elevation from the position of reader in fermentation processes to professorial status. More recently, the work of his school has received further stimulus from the fact that with the growing recognition of the need for further technological education the Manchester College is being expanded to provide, among other improved facilities, an enlarged school of biochemistry with excellent facilities both for research and teaching. Quite apart from his valuable material services to science, Prof. Walker will take with him into retirement the exceptionally high personal regard of a large number of former students and colleagues.

Prof. A. A. Eddy

The Councils of the University of Manchester and the Manchester College of Science and Technology have approved the appointment of Dr. Alan A. Eddy to the chair of biochemistry in the Faculty of Technology from January 1, 1959, in succession to Prof. T. K. Walker. Dr. Eddy, who will be thirty-two on taking up his appointment, was educated at Devonport High School and entered the University of Oxford with an open scholarship in natural science in 1945. He graduated in chemistry with first-class honours and later undertook research under Sir Cyril Hinshelwood into the metabolism of alkali metal ions by bacteria, which formed the subject of his thesis for the D.Phil. degree. Having been awarded an Imperial Chemical Industries Research Fellowship, he afterwards participated in the well-known work of Sir Cyril's school on the adaptive behaviour of micro-organisms. In 1954 Dr. Eddy joined the staff of the Brewing Industry Research Foundation, later assuming responsibility for the department of microbiology in which, under the successive directorship of Sir Ian Heilbron and Dr. A. H. Cook, he was able to develop his interest in the chemical aspects of yeast structure. In this connexion his work on the wall of the yeast cell may be specially mentioned as throwing new light on various important aspects of the behaviour of yeast during industrial fermentations, while his development of methods for isolating nuclear bodies from yeast represents an outstanding achievement in a more academic field. Dr. Eddy is the author or joint author of a large number of original memoirs and, in keeping with his future responsibilities, he has been closely associated with various projects for developing the application of continuous methods of fermentation, a subject of growing importance in the industrial field.

Frederick Soddy Memorial Plaque

On October 25, Eastbourne was visited by members of the Soddy Memorial Trust, whose chairman, Sir Gerald Campbell, invited the mayor, Councillor J. W. G. Howlett, to unveil a memorial plaque on the house in Bolton Road where Frederick Soddy was born and passed his early austere and motherless days. At a previous commemoration luncheon, Councillor Howlett expressed the pride of the town in its famous son, who had predicted the wide-scale use of energy from the atomic nucleus. Following a well-attended film show arranged by the Institute of Atomic Information, the Trustees visited Eastbourne College, where Dr. F. M. Brewer was invited to unveil a memorial plaque in the new Soddy Senior Chemistry Laboratory, a notable extension of the laboratories where Soddy began his chemical studies ; it has recently been provided by the Industrial Fund for the Advancement of Scientific Education in Schools.

The Second Soddy Memorial Lecture was given by Dr. F. M. Brewer, of the Inorganic Chemistry Laboratory, Oxford, where he became a pupil of Soddy in the early 1920's. He recalled many personal facets of the formulator of the theory of disintegration and of the displacement law, which culminated in the establishment of isotopy and radiochemistry. Soddy always exhibited a great natural charm and generosity of thought, he said, especially towards his students and those with whom he collaborated, which persisted throughout his life and was augmented by the outstanding sociability of his wife. Soddy made little immediate impression on the authorities at Oxford, however, and his extensive work during the First World War at Aberdeen was cut short. Thereafter he became a passionate advocate of the widest use of science for furthering social progress. The local and national neglect of applied science prompted him to investigate political and monetary systems, which provoked academic criticism. Soddy was widely cultured, a mountaineer, an explorer of knowledge in other fields, and a man of the highest integrity, particularly when attributing priority to scientific discoveries and their interpretation. He remains a great man and a fundamental pioneer towards the utilization of nuclear energy. His impact on science is fully documented in "The Life Story of Frederick Soddy", by Muriel Howorth, the first copy of which was presented to the Eastbourne College Library by the author.

Windscale Pile No. 2

The Atomic Energy Authority has decided not to restart Windscale Pile No. 2. The cost of the measures which Sir Alexander Fleck's Technical Evaluation Committee recommended should be taken before restarting Pile No. 2 would be in the region of £500,000. If this cost were incurred and the pile restarted, the plutonium produced over the estimated remaining life of the pile would be extremely expensive. Plutonium is now being produced in substantial quantities from the Calder Hall reactors, and the Chapelcross reactors will come into operation during the next year. The fuel will now be discharged and reprocessed for other uses ; equipment will as far as possible be removed, and certain of the buildings will be useful for experimental purposes, saving expenditure which would otherwise have been necessary. This decision will not give rise to any redundancy. The programme of work of the chemical processing plant at Windscale is increasing, and the workers employed on the two piles will be re-allocated to other work.

Use of Radioactive Substances and X-rays in Schools

The Minister of Education, in Administrative Memorandum No. 577 (October 1958) to local education authorities and secondary schools, has announced that, although such work is normally more appropriate to university courses, a small number of schools are introducing demonstrations and experiments involving radioactive substances and sources of X-rays. In view of the possible risks to health of those engaged in such work, and after consultation with the Radioactive Substances Advisory Committee and the Atomic Energy Authority, it has been decided that special authorization will have to be obtained by any school wishing to conduct such work. The Minister will grant authorization, which will be reviewed annually, only where he is satisfied that the necessary safety precautions are maintained. The Minister also requires that he be notified by all schools employing X-ray and other apparatus operating at voltages greater than 5 kV., so that the appropriate protective barriers may be specified, without which such apparatus may not be used. Notes for the guidance of schools in the use of radioactive materials and of equipment producing X-rays have also been issued.

Wellcome Trust: Grants for Research

The Wellcome Trustees have announced that among the grants made during the half-year ended August 31 were the following : up to £60,000 to the Post-graduate Medical School of London for the cost of including a Wellcome Research Library in the proposed new buildings ; up to £37,000 to the Institute of Psychiatry, Maudsley Hospital, to provide laboratories in which integrated research by the Departments of Neuro-endocrinology and Neuropathology may be carried out ; up to £36,500 to the Department of Anatomy, University of Birmingham, to extend the research laboratories and animal accommodation ; up to £25,000 to the Department of Zoology, University of Edinburgh, to provide additional research accommodation ; £50,000 to the University of Western Australia to endow a Wellcome Research Department of Pharmacology ; up to £17,000 to the Institute of Medical Research, North Shore Hospital of Sydney, Australia, to build and equip laboratories for experimental medicine and surgery. In addition, three electron microscopes are being purchased at a cost of approximately £34,000 for indefinite loan to the following institutions: the Biophysics Research Unit of the Medical Research Council, King's College, London (Prof. J. T. Randall) ; Sir William Dunn School of Pathology, University of Oxford (Sir Howard Florey) ; London School of Hygiene and Tropical Medicine.

Australian Society of Plant Physiology

AT the University of Adelaide on August 19, plant physiologists from all the States of Australia attended a meeting convened by Dr. R. N. Robertson, head of the Plant Physiology Unit of the Commonwealth Scientific and Industrial Research Organization in Sydney, to consider the formation of an Australian Society of Plant Physiologists. The sixty scientists present decided unanimously to constitute such a society, with the aim of advancing the science of plant physiology. A constitution was adopted requiring the newly formed society to hold at least one annual meeting which will include a session for the presentation of scientific papers. At the inaugural meeting the following officers were elected. *President*, Prof. J. G. Wood (Department of Botany, University of Adelaide), *Secretary*, Dr. L. H. May (Waite Agricultural Research Institute, Adelaide). *Treasurer*, Dr. L. G. Paleg (Waite Agricultural Research Institute, Adelaide), *Committee Members*, Dr. N. P. Kefford (A.C.T.), Mr. L. A. Thomas (Queensland), Dr. J. F. Turner (New South Wales), Dr. P. Brownell (South Australia), Dr. D. M. Paton (Tasmania), Dr. D. J. Carr (Victoria), Prof. B. J. Grieve (Western Australia).

Some scientific papers were also presented at the inaugural meeting, and these indicated the wide range of interests of Australian physiologists. Nitrogen metabolism and the mechanism of ion uptake by plant cells, which have long been under study in Adelaide and Sydney respectively, were discussed in the light of recent work. Growth regulators formed the basis of several papers, ranging from synthesis in a symbiotic association, effects in photoperiodic and vernalization responses, to their effects in root contraction. Translocation, plant cell structure, sodium nutrition and the dynamics of growth in seedlings were among other topics presented. Abstracts of all the papers will be published in the *Australian Journal of Science*. At the next meeting, to be held in Canberra, it is planned to include agronomic and horticultural topics of interest to plant physiologists.

Forests Products Research Laboratory

THE Council for Scientific and Industrial Research has set up the following Steering Committee to look after the research programme of the Forest Products Research Laboratory, in place of the Forest Products Research Board : Dr. B. K. Blount, deputy secretary of the Department of Scientific and Industrial Research (*chairman*) ; H. Douglass, a member of the Research Council and general secretary of the Iron and Steel Trades Confederation ; L. J. Cardew Wood, managing director of Bell's Asbestos and Engineering, Ltd., and director of Bell's Asbestos and Engineering (Holdings), Ltd. ; the director of the Forest Products Research Laboratory (Dr. F. Y. Henderson) ; H. Wooldridge, head of the Stations Division, Department of Scientific and Industrial Research. Its terms of reference are : (1) to be responsible to the Research Council for the selection of projects and for the allocation of effort to them, within the financial resources allocated to the Laboratory and such other limits as may from time to time be imposed by the Council ; (2) to report annually to Council, submitting a research programme for the following year. The Committee, which will be a full committee of the Research Council, is empowered to set up specialist sub-committees to provide technical advice on particular fields of work and especially on research in the field of pulping.

Future of Timber Research in the United Kingdom

FOLLOWING recent announcements of its policy on forest products research, the Council for Scientific and Industrial Research recommends that the ultimate objective should be to concentrate all timber research at Princes Risborough, the site of the present Forest Products Research Laboratory. This would avoid the danger of overlap and unnecessary expense that might arise if separate laboratories were developed in different localities to serve the sectional interests of the timber trade and would ensure that the most effective use is made of the qualified staff and material resources available in the various organizations concerned with timber research. Discussions are being held with the Timber Development Association and the Forestry Commission to determine the type of organization which would most effectively co-ordinate the research requirements of their interests. As an initial step to the achievement of this objective, the Department of Scientific and Industrial Research is discussing with the Timber Development Association the possibility that part of the Princes Risborough site might be made available to the Research and Development Committee of the Association for immediate development, without prejudice to work at present in hand at its existing laboratories. Discussions will shortly be held with other trade organizations interested in timber research.

Royal Observatory, Cape of Good Hope

IN his report for 1957 H.M. Astronomer at the Cape of Good Hope records continued progress in many branches of astronomy (pp. 9. Cape of Good Hope : The Observatory, 1958). On the administrative side the increase in the number of visiting astronomers from outside South Africa and the growing co-operation between the Cape and Radcliffe Observatories are both valuable developments. The routine work of the Cape Observatory is undoubtedly the most important, and in some fields it is the only work of its kind being done in the southern hemisphere. The meridian circle programme of observations of about seven thousand stars is approaching completion, and a new working list of faint stars for use as standards in photographic plate reductions is being prepared. The preparation for press of the "Cape Photographic Catalogue", zones −56° to −60° and −60° to −64°, has been completed; astrometric work on the zone −64° to −68° was completed in 1955 and the photometric work for this zone is almost finished. Position measurement for 4,400 stars in the −68° to −72° zone was completed, and proper motion and magnitude measurements are in progrsss. Preliminary work has been undertaken in all the remaining zones to the south celestial pole, involving 9,500 stars in all. A large programme of photoelectric photometry is under way with several telescopes. Magnitudes are being determined for many standard stars, stars on radial velocity programmes, parallax stars, stars in selected areas, comparison stars for cepheid variables, southern stars in the "Yale Bright Star Catalogue", and for other interesting objects. More than 7,000 observations were made during the year; more than 50,000 images were measured in a programme of photographic photometry, and other routine observations of the Sun, variable stars and occultations were continued. The radial velocity work at the Radcliffe Observatory was concerned with nearby stars, stars in the southern galactic cap and standard stars. Some miscellaneous observations were made on extragalactic nebulae, and the first section of the "Cape Photographic Atlas of Southern Galaxies" was published during the year.

Society of Protozoologists

The following elections have recently been made by the Society of Protozoologists: *President*, Dr. Elery R. Becker (Arizona State College); *Vice-President*, Dr. Norman D. Levine (University of Illinois); *Secretary*, Dr. John O. Corliss (University of Illinois); *Treasurer* (retained), Dr. Daniel M. Lilly (St. John's University, Jamaica, New York); *Editor* and *Acting Editor* of the *Journal of Protozoology* (both retained), Dr. William Trager (Rockefeller Institute) and Dr. Seymour H. Hutner (Haskins Laboratories, New York City); *Honorary Member*, Dr. Emmanuel Fauré-Fremiet (Collège de France, Paris). The Society will hold its next annual meeting with the American Institute of Biological Sciences in August 1959 at Pennsylvania State University.

The Night Sky in November

New moon occurs on Nov. 11d. 06h. 34m. U.T., and full moon on Nov. 26d. 10h. 16m. The following conjunctions with the Moon take place: Nov. 13d. 16h., Saturn 4° S.; Nov. 25d. 07h., Mars 3° N. In addition to these conjunctions with the Moon, Mercury is in conjunction with Antares on Nov. 11d. 12h., Mercury being 2·1° N. Mercury and Venus are too close to the Sun for observation. Mars rises at 17h. 25m., 16h. 05m. and 14h. 45m. at the beginning, middle and end of the month, respectively, setting on these dates at 8h. 55m., 7h. 30m. and 6h. 10m.; conditions for observation are very favourable. Mars reaches opposition on November 16, when its distance is 46 million miles and its stellar magnitude −2·0. Mars continues to retrograde, moving from Taurus into Aries on November 22. Jupiter is too close to the Sun for observation. Saturn may be visible low in the south-west after sunset, but conditions for observation are not favourable. Occultations brighter than magnitude 6 are as follows, observations being made at Greenwich: Nov. 2d. 02h. 17·1m., 26 Gem. (*R*); Nov. 3d. 01h. 43·4m., 68 Gem. (*R*); Nov. 27d. 20h. 58·6m., 115 Tau. (*R*); Nov. 29d. 23h. 05·0m., λ Gem. (*D*); Nov. 30d. 00h. 17·9m., λ Gem. (*R*). *R* and *D* refer to reappearance and disappearance, respectively. The Taurid meteors are active during the first fortnight of the month, conditions being favourable; the radiant is near R.A. 3h. 36m., Dec. +14°. The Leonid meteors are active on November 15–17, conditions being favourable; the radiant is near R.A. 10h. 08m., Dec. +22°.

Announcements

Mr. W. A. Dutton, assistant director of the Hosiery and Allied Trades' Research Association, Nottingham, and Mr. H. Marsden, Universal Winding Co., Ltd., Manchester, have been awarded the Institute Medal of the Textile Institute. This Medal was inaugurated in 1921 as an award by which recognition could be given for distinguished service to the textile industry in general and to the Institute in particular.

Trinity College, Cambridge, offers entrance exhibitions to male students of universities in the British Commonwealth to enable them to read for the degree of B.A., or LL.B., or for a diploma. Further information can be obtained from the Senior Tutor, Trinity College, Cambridge.

A conference on Electronic Digital Computers and their Industrial Applications will be held in the Department of Mathematics, Birmingham College of Technology, on December 10, when members of IBM, Ltd., will speak on the following topics: data processing machines available; commercial applications on IBM 650; technical applications including linear programming; organization and preparation for electronic data processing. During the course of the day, three 16-mm. sound films to illustrate IBM machines will be shown. The conference fee is £2, and further details and application forms can be had from the Registrar, College of Technology, Gosta Green, Birmingham 4.

The Faraday Society Bourke Lectures will be delivered by Prof. R. H. Stokes (University of New England, Australia). The lectures will be: "Tracer Diffusion and Self-diffusion in Concentrated Electrolytes", in the Main Lecture Theatre, Chemistry Department, King's College, Newcastle on Tyne, on November 14, at 5.30 p.m. (chairman: Prof. W. F. K. Wynne-Jones); and "The Relation between Ion Mobility and Viscosity in Aqueous Solutions", in the Chemistry Department, University of Glasgow, on November 18, at 4 p.m. (chairman: Prof. J. Monteath Robertson). The second lecture will also be given at the Edward Davies Chemical Laboratories, University College of Wales, Aberystwyth, on November 20, at 5.15 p.m. (chairman: Prof. C. W. Davies). Further information can be obtained from the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

We regret that in referring to the appointment of Sir Rudolph Peters as president of the International Council of Scientific Unions (*Nature*, October 11, p. 990), he was wrongly described as lately director of the Agricultural Research Council Institute of Animal Physiology; Sir Rudolph is, in fact, head of the Biochemistry Department of the Institute.

Erratum. In the communication entitled "Stability of Evaporated Films", by M. Wyn Roberts, in *Nature* of October 25, p. 1151, par. 4, line 11, for "33×10^{-3} cm.^{3} (S.T.P.)" read "13×10^{-3} cm.^{3} (S.T.P.)".

THE CHEMICAL RESEARCH LABORATORY

REPORT FOR 1957

THE report of the Director of the Chemical Research Laboratory which accompanies the report of the Chemistry Research Board under the title "Chemistry Research, 1957"* is the last which will cover the work of the laboratory under that title, which has now been changed to the National Chemical Laboratory, and the Board itself was being disbanded on September 30 and replaced by a Steering Committee. The new unit at Harwell, which is to co-operate with the Atomic Energy Authority, is studying possible applications of radioisotopes and began work there on October 1, 1957. To permit extension of the programme carried out for the Authority on the extraction of radioactive elements from minerals and ores the Authority is extending the Radiochemical Building and increasing the staff engaged on its behalf. The Authority is also contributing to the intensification of work on chelating and complexing resins. After a critical review during the year of the scheme of providing standard organic compounds, the Board agreed that the charges made for pure standard samples should fully cover the cost of the service, and to economize scientific effort recommended that the preparation of standard materials should be limited to those not available by purchase elsewhere. The Board's report also emphasizes the urgent need to expand work in the inorganic field.

The Director's report notes the increased effort given during the year to the work on the extraction, concentration and purification of elements from ores and low-grade materials, the preparation of ion-exchange membranes and the synthesis of complexing resins. Among advances to which he directs particular attention are the construction of three experimental water-circulating systems to study the failure of tubes by corrosion, in water-circulating systems of modern engineering projects, and the development of an experimental technique to give reproducible results. The formation of an absorbed film and the subsequent growth of an oxide film have been followed by radiometric methods. A rapid method has been developed of concentrating the less plentiful constituents of rare-earth mixtures using a partial chromatographic technique, and further studies of zone-refining have shown that with tellurium, indium, tin and antimony the method is not effective in removing all the impurities as required by the electrical industry. The possibility of recovering germanium from ammoniacal liquor has also been examined. Advances are reported with resin-in-pulp and solvent extraction processes for extracting and recovering uranium and thorium from ores, and an ion-exchange phosphorylated cellulose has been developed for recovering thorium from sulphate solutions of monazite as well as a field method, which can be used by relatively unskilled personnel, for determining as little as 0·001 p.p.m. of uranium in river water.

The work of the Organic Group has included a new study of the synthesis and application of certain organo-metallic compounds with special reference to the preparation of materials of high thermal stability, further work on the isomerization of ethyl*cyclo*pentane, the reactions of nascent carbon-14, the rearrangement of dipotassium salicylate and hydrazine polymers and the polymerization of aromatic *iso*cyanates. Progress is reported in the purification and measurements work, including the construction of a high-voltage paper-electrophoresis apparatus and apparatus for the direct measurement of latent heats of vaporization and specific heats of vapours. Encouraging progress is also reported in the preparation of new types of ion-selective membranes, and cation- and anion-selective membranes based on polyvinyl chloride have shown very promising mechanical and electrochemical properties. In fractionating polymers it has been found that ^{14}C-labelled polysarcosine dimethyl amides of molecular weights up to about 12,000 can be separated by paper chromatography using gradient elution, and studies on the random partial sulphonation of cross-linked polystyrene promise to throw light on the fundamental mechanism of ion-exchange.

A comprehensive collection of organisms used in the assay of amino-acids was built up in the National Collection of Industrial Bacteria during the year. Pilot-plant trials of the microbial production of sulphur from sulphate-enriched sewage sludge in progress at the London County Council's Northern Outfall Works at Beckton have confirmed earlier laboratory experiments in that the final sludge 'dewaters' more efficiently than sludge digested from methane. The great reduction in the volume of solids for disposal and consequent saving in transport costs may have an important influence on the economics of the process. Other work by the Microbiology Group has been concerned with the microbial formation of methane and with the bacterial oxidation of aromatic compounds, including benzenesulphonic acid and catechol, and the perfusion apparatus described in the 1956 report has been used to satisfy requests from industry for organisms capable of destroying such recalcitrant chemicals as methylated and unmethylated aryl sulphonates, thiocyanates and β-naphthol.

The Chemical Engineering Group is studying the rate of solution of gases in agitated liquids and has devised an optical device for measuring the interfacial area in gas–liquid dispersions. It has also obtained valuable data on the evaluation of mass transfer coefficients.

About 10 per cent of the time of senior staff is occupied with advisory work, and at the end of the year the total staff, including 58 scientific officers, 86 experimental officers, 34 assistants (scientific) and 2 works technical officers, numbered 239 compared with 223 at the end of 1956. Appendixes list the staff in post on December 31, 1957, as well as the committees of the Board, patents publications during the year, standard samples of organic compounds and organisms deposited in the National Collection of Industrial Bacteria.

SALT AND WATER BALANCE IN ANIMAL LIFE

THE mechanisms by which salt and water balance is maintained in the majority of the groups of cœlomate animals are now fairly well understood. Such mechanisms are of importance not only in all freshwater animals, which must always protect themselves against the continual loss of salts and the uptake of water, but also in many marine animals, where it is found that the salt and water content of the body is also carefully regulated. There are, however, many aspects of the functioning of these mechanisms about which very little is known at present. For example, salt balance is generally maintained by the activity of a specialized group of cells which are localized, often in the respiratory membranes, and which are capable of doing work to sustain a gradient of salt concentration across the membrane. Although the gross location of these cells can generally be inferred, we still have very little knowledge of their nature and properties at a cytological level. Histological and cytochemical studies under conditions of varying salt concentration can help in their identification and characterization.

The quantitative measurement of salt and water movements in animals is another important aspect which, as yet, has received little attention. It is only by such measurements that it is possible to discover the factors upon which these movements depend and the extent to which they can be regulated and controlled by the animal itself. The general availability of radioactive and other forms of tracer substances has now made this type of measurement much easier.

Both cytological and quantitative investigations of the mechanisms of salt and water balance in animals were considered in a symposium under the above title which was held as a joint session of Sections *D* and *I* (Zoology and Physiology and Biochemistry) at the British Association meeting at Glasgow on September 1.

Dr. T. Vickers (University of Cambridge) took up once again the question of the cells responsible for salt secretion in the teleost fish. Nearly thirty years ago Homer Smith showed that in the marine teleosts salt and water balance is achieved by the ingestion of large amounts of sea-water, the intestinal absorption of water and salts from this and the subsequent extrarenal excretion of the excess salt. Keys demonstrated that this salt was secreted by the gills, and Keys and Willmer identified large eosinophil cells in the branchial epithelium of the eel and suggested that these cells were responsible for salt secretion. Vickers showed that a similar type of cell appears in the gill lamellæ of the brackish- and fresh-water guppy, *Lebistes reticulatus*, when this is adapted to salt solutions. Under these conditions, small, previously undifferentiated cells are mobilized and they develop into large eosinophil cells the size of which depends on the salt load. They appear to be active cells with many mitochondria but give negative tests for mucus when fully developed. During the normal development of these cells they have small pits at their distal ends which are mucus-positive but which disappear as the cell enlarges. It is interesting that if the animal fails to adapt itself to the new salinity these pits enlarge and become filled with mucus, the cell cytoplasm becomes reduced and the cell now strongly resembles a normal goblet cell. It is clear that in this epithelium transformation from one functional cell type to another can take place. The primary stimulus for the formation of the salt-secreting cell is presumably the increase in salt load, but whether this can directly affect the branchial epithelium or whether the response is induced indirectly is not yet known.

That it is possible to induce a transformation of epithelial cells directly was demonstrated by Dr. H. B. Fell (University of Cambridge). She showed that vitamin A controls the differentiation of certain types of epithelia, the respiratory epithelium being especially susceptible. Thus, for example, the epithelium of the trachea is composed typically of columnar, ciliated and mucous cells. In the absence of vitamin A the ciliated and mucous cells disappear and a squamous epithelium is formed. The direct nature of this effect can be demonstrated by the behaviour of embryonic chick skin in tissue culture. A keratinizing epithelium of the squamous type is formed in a normal culture medium, but if vitamin A is present the keratin process is suppressed and the cells produce a mucous secretion. In some cases ciliated cells may also be produced. If the tissue is returned to the normal medium, after a few days of intensified secretion the basal cells proliferate and the squamous epithelium is regenerated.

Dr. R. Morris (University of Nottingham) showed that cell changes occurred in the respiratory epithelium of the river lamprey, *Petromyzon fluviatilis*, also. He described how the adult lampreys, which are found in the sea and in estuaries, come upstream to spawn and during the process lose their marine osmoregulatory mechanism, replacing it by a freshwater one. Animals taken from fresh water vary greatly in their behaviour in 33 per cent sea-water. Mature animals lose much water and their blood concentration rises to that of the outside solution. The fresh-run animals are very variable: some behave like mature animals, whereas others are able to maintain both salt and water balance. In the latter case, the mechanism closely resembles that found in the marine teleost and, in fact, the lampreys only differ in their greater water permeability. Just as in the marine teleost the gill epithelium contains salt-secreting cells, but its nature is variable. In many fresh-run animals the secreting cells are regressing and other cells, which are typical of the freshwater animals, are taking their place. The breakdown of the marine mechanism involves not only the disappearance of the secretory cells but also the loss of swallowing capacity as the animal ceases to feed in fresh water and the gut degenerates and there is an increase in permeability of the body surface.

The lampreys probably developed in fresh water and evolved their marine osmoregulatory mechanism quite independently of the teleosts.

The extent to which a knowledge of the mechanism of salt and water balance in the lower vertebrates, such as the cyclostomes and fishes, can assist in deducing the type of habitat in which the vertebrate group as a whole evolved was discussed by Dr. J. D. Robertson (University of Glasgow). A widely held view, due mainly to Homer Smith and Marshall, is that certain features of these mechanisms, especially the presence of the peculiar glomerular kidney, point to a freshwater origin for the vertebrates. Robertson challenged this view. He showed that the palæontological evidence indicates that the earliest vertebrates, the Ostracoderms and the Acanthodians, lived in the coastal waters of the sea, and their remains, found in the rocks of the Ordovician and Silurian periods, are mostly associated with known marine invertebrates. At the same time, geochemical evidence suggests that the seas in Ordovician times were probably almost as saline as they are to-day. Robertson claimed that the inferences which could be drawn from the physiological features of present-day vertebrates are not opposed to this view. He brought forward the fact that all non-vertebrate chordates are marine and their blood composition, where known, is similar to that of sea water. Although the salt content of the blood of almost all the aquatic vertebrates is much less than that of sea water, the blood of the myxinoid cyclostomes—a very primitive vertebrate group—is not dissimilar, and this may be a primary feature. Finally, he suggested that the glomerular kidney is not necessarily a freshwater adaptation. It may well have existed in marine protovertebrates as it does to-day in the marine elasmobranchs and myxinoids. In these marine animals the glomerular filtration surface may be practically as large as that of the freshwater teleosts.

There seems little to be gained by pursuing this question further until new facts have come to light. On the physiological side, many more studies on the quantitative aspects of renal function in the cyclostomes and fishes would do much to increase our knowledge on this fundamental issue.

A quantitative approach to the problems of salt balance was adopted by Dr. J. Shaw (King's College, Newcastle), who described an analysis of sodium uptake by the freshwater crayfish, *Astacus pallipes*. A steady state is achieved when the normal sodium loss is balanced by an equal uptake of sodium from the environment. The rate of sodium uptake can be conveniently measured by the use of a radioactive sodium isotope. The rate of sodium uptake depends on the external sodium concentration and a maximum rate is approached at concentrations as low as 1 m.mole/l. Above a certain minimum value balance can be achieved at any external concentration, since the uptake-rate is also regulated by the internal sodium concentration. A fall in the blood sodium concentration of 10 per cent or less may increase the rate of uptake by as much as five times. The system is a self-regulating one and results in the maintenance of the blood sodium concentration despite changes in the sodium content of the environment or the presence of other factors which may affect the sodium uptake-rate.

J. Shaw

AQUATIC AND AIR POLLUTION

A SYMPOSIUM on "The Effects of Pollution on Living Material", organized by the Institute of Biology, was held at the rooms of the Royal Geographical Society on September 25 and 26. The general and scientific interest in various aspects of this subject may be gauged from the fact that 380 registrations were received, more than a hundred of which were from industrial organizations, public authorities and similar bodies. The symposium was divided into four sessions, each dealing with one separate aspect of the problem: these were river, estuarine and air pollution, and pollution by radioactive substances.

In the field of air pollution the immediate need is clearly to study its effect on man, but there was evidence at this symposium that other aspects of the problem are not being neglected. Recent studies by Gorham[1] suggest that air pollution is increasing the concentrations of sulphuric acid in atmospheric precipitation in the Lake District and "will presumably hasten deterioration of already heavily leached Lake District soils". Moorland and high tarn communities may well be affected. Changes of this sort brought about by air pollution, though difficult to study except in local areas and special habitats, may be widespread.

Before about 1945 the biologist studying water pollution was primarily interested in the effects of polluting discharges on river and estuarine communities. The change in community structure often gave a useful measure of the severity of the pollution. The mode of action of the pollutants which resulted in such changes was rarely studied and, with the exception of organic pollution associated with low oxygen concentrations, practically no information was gathered on how these selective forces operated at organismic level. This state of affairs is generally true to-day, although a recent advance has been made concerning the chemical factors important in the distribution and deaths of fish in a sewage effluent channel[2].

Since the end of the Second World War, however, there has been an increasing interest in the effects of organisms on the polluted environment. In pollution by radioactive wastes, although there is no evidence of changes in community structure, the activity of organisms in accumulating and afterwards releasing radioisotopes is of the utmost importance in determining permissible discharges. In the field of 'conventional' water pollution similar trends are evident, and it seems likely, from the papers presented, that in the near future it will be possible to make estimates of some of the effects which organisms have on their environment.

The first speaker in the session concerning river pollution, Mr. F. T. K. Pentelow (Ministry of Agriculture, Fisheries and Food), began by admitting the difficulty of defining pollution. It could be said, however, that water is polluted when it becomes unfit for some use to which it could be put in its natural state. Mr. Pentelow directed attention to the many improvements which have occurred in British rivers over the past thirty years at a time of great industrial and urban expansion in spite of a major slump, rearmament, war, and a series of financial crises. Pollution, though now perhaps more widespread, is not nearly so intense as at the beginning of this period. Mr. Pentelow considered that an important factor leading to further improvement has been the recent formation of river boards and their endowment with statutory powers of control.

Mr. H. B. N. Hynes (University of Liverpool), discussing the biological effects of water pollution, suggested that the effects vary with the age of the phenomenon which the pollution produces. Man-made types of pollution, such as the discharge of poisons, which have no counterparts in natural ecological systems, result in an elimination of species, whereas other types, such as organic and thermal pollution, result in the development of replacement communities adapted to the peculiar ecological conditions. These observations seem to provide a useful basis for an ecological classification of pollutional effects. Dr. Hynes suggested that a controlled introduction of selected organisms tolerant of the somewhat higher temperatures found near discharges of cooling water from power stations might be considered. There are severe objections to such introductions, however, some of which were raised by the delegates present.

Mr. D. F. Westlake (Freshwater Biological Association) described recent studies made to assess some of the effects which plants and invertebrates have on stream conditions. It was shown that these organisms have quite large effects on the oxygen regime of organically polluted streams where high densities of bottom-living invertebrates and often large growths of macrophytic vegetation, especially *Cladophora*, occur. Estimates of these changes in the concentration of dissolved oxygen based on field observations were presented, together with descriptions of experimental studies of the effects of some invertebrates on bottom deposits. Physical effects of plant growth in streams were also discussed.

In the discussion which followed this session, Mr. F. W. Roberts (Luton Sewage Works) described his experiments on the effects of detergents on aquatic plants and reported that when grown in concentrations of 2·5 p.p.m. of anionic detergents, certain plants, such as *Ranunculus* and *Apium*, showed browning and loss of leaves. A non-ionic detergent did not have the same adverse effects. The tolerances of different plant species to detergents reflected their natural distribution in the river system with which he was concerned.

The second session, dealing with estuarine pollution, was introduced by Dr. B. A. Southgate (director, Water Pollution Research Laboratory), who said that British estuaries were generally in a worse condition than the rivers. He attributed this principally to differences in legislation and to past over-assessment of the capacity of estuaries to deal with pollution.

The first two speakers in this session, Mr. A. B. Wheatland and Mr. A. L. H. Gameson (Water Pollution Research Laboratory), discussed some aspects of the carbon, nitrogen and sulphur cycles in the Thames estuary. Mr. Wheatland described his investigations on denitrification and particularly the influence of low concentrations of dissolved oxygen and organic matter on this process. Some of the factors affecting the formation and oxidation of hydrogen sulphide were also described. Mr. Gameson discussed the importance of the biochemical reduction of nitrate and sulphate, and photosynthesis by phytoplankton, in contributing oxygen to the Thames Estuary. The reduction of nitrate produced about 140 tons of oxygen daily, that is, roughly one-quarter of that supplied by absorption from the atmosphere. Sulphate reduction and photosynthesis would seem to play a minor part in the oxygen balance of this estuary.

The final speaker on the first day, Prof. G. E. Newell (Queen Mary College, London), confining his remarks to lower estuaries, described the eutrofication resulting from organic pollution and its enrichment of the fauna and microflora. It was shown how hydrographic characteristics of estuarine basins and condition of the deposits may influence these pollutional effects.

In the discussion which followed, Mr. R. Bassindale (University of Bristol) showed how difficult it was to decide, in any given case, how far pollution was responsible for the reduction in fauna in the middle reaches of an estuary, for fluctuations in salinity in these areas result in a similar faunal reduction, and pollutional effects are generally superimposed on natural salinity effects.

The morning of September 26 was devoted to a series of papers on air pollution. The first speaker, Dr. E. T. Wilkins (Fuel Research Station), described the methods of measurement of deposited matter, sulphur dioxide, and smoke, and commented upon the value of the instruments employed for this purpose—now almost 3,000 in Great Britain—in monitoring suspected sources of excessive pollution and assessing local and national trends. Dr. Wilkins described measurements of toxic constituents of motor-vehicle exhausts, the most harmful of which appears to be carbon monoxide, which reaches concentrations of 50 p.p.m. at breathing height in London streets congested with traffic. The general conclusions of smog studies were outlined and possible synergistic effects of smoke, sulphuric acid and other complexes were discussed. The possibility of neutralizing acid gases in smog by the controlled addition of ammonia is being explored.
